EFFECT OF TOPOGRAPHIC AND GEOLOGIC HETEROGENEITIES ON THE DISTRIBUTION PATTERN OF AQUIFERS IN AKWA IBOM STATE, SOUTHEASTERN NIGERIA.

E. U. EGEH, C. S. OKEREKE and O. O. OLAGUNDOYE

ABSTRACT

Geologic heterogeneities and topographic variations in relation to aquifer distribution and occurrence in Akwa Ibom State have been assessed based on geologic and geophysical studies Sixty-six sounding points together with electric log responses of representative wells together with surface geologic data have been integrated and used in deciphering subsurface variations in hydrologic unit in the state. The results show that three aquiferous units, made up of medium to coarse grained whitish sands exist within a depth range of 72 to 98 metres and having resistivities less than 1500 ohm metres. These aquifers are clearly defined in those locations close to the coast and in the hinterlands whereas towards the northern parts of the state they appear to pinch-out or dip downward to much greater depths. Measurements of elevation across the study area show a drastic decrease in altitude tending toward the mean sea level—within the hinterland and coastal regions, whereas towards the northern part, relatively higher elevations-exist. The increase in altitude in addition to the occurrence of thick columns of compacted shales greatly account for the scarcity of aquiferous zones in this northern part of the study area contrary to the localities within and surrounding the coastal and central regions.

Key words: Heterogeneities, aquifer, topography, pinch-out, hydrologic.

INTRODUCTION

This paper outlines the effects of geologic heterogeneities and topographic variations on the distribution patterns of aquifers in parts of Akwa Ibom State, southern Nigeria (Figure 1). According to Esu et al (1999), the estimated areal extent of the state is about 6500km and it lies within longitudes 7°30' and 8°21' East and latitudes 4°30' and 5°30' North. The area belongs to the low-lying coastal/deltaic plains of Southern Nigeria (Masasan and Quinn-Young, 1977).

This paper considers in regional terms the aquifer delineation and distribution in parts of the area. The paper therefore attempts to adduce reasons for the uneven distribution of ground water in the area given the fact that the study area lies within the same geologic and geographic provinces. It is therefore not uncommon to document numerous failed water projects in some parts of the area whereas greater success records abound in some other parts. It is the intent of this paper to unravel the mysteries surrounding this observation and to proffer a more appropriate remedy for the water supply problems to the inhabitants of these hydrogeologically 'hostile' environments within the study area.

Significantly, the initial site appraisal vis-àvis groundwater development schemes in the study area from this report is very possible. In this regard, it would be possible to pre-empt and anticipate the perculiar condition(s) of the field remediation steps adopted to achieve success.

In carrying out this study, a two month intensive geological mapping, surface resistivity surveys as well as downhole borehole logging were done in 20 Local Government Areas of the state (table 1) which considered quite representative.

GENERAL GEOLOGY

The geology of Akaw Ibom has been extensively studied by many workers among whom are Amajor (1986), Petters (1989), Esu et al. (1999), Inyang (1995), Effanga and Chuku (1995). According to these authors, the area belongs to the southern pars of the Cretaceous to Teritary sedimentary basin of Southern Nigeria, including parts of the lower Benue Trough and the Niger delta (Figure 2). The area is underlain by Maastrichtian to Pleistocene sedimentary rocks dipping 6-10° southwest (Esu et al., 1999). According to these authors, the late Cretaceous and early Tertiary, comprising the Ajali and

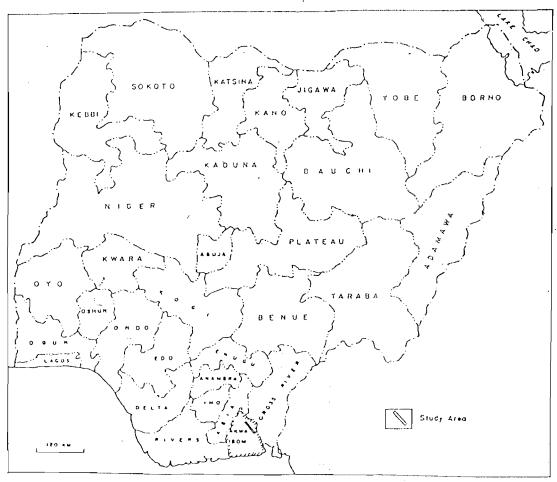

Figure 1 Map of Nigeria showing Akwa Ibom State with study Area

Nsukka Formations, the Imo shale and Ameki Groups underlie a strip, about 3 to 15km wide in the northeast, forming the northern part of the Calabar Flank (Figure 2). These strata are more extensively developed in the Anambra Basin further northwest of the present study area. It is also evident that more than 85% of the study area is underlain mainly by Neogene and Quaternary sediments of the Niger Delta which comprise the Ogwashi-Asaba and Benin Formations. As shown by Inyang 91995) and Esu et al (1999). The geological succession, of the area consists mostly of shales, sandstones. sands and representing the transgression and regression episodes which characterized the development of southern Nigeria sedimentary basin. The shales generally thicken northwards whereas down to the coastal regions, sands of various sizes predominate.

METHODOLOGY

After a preliminary general geological

mapping of the study area, sixty sounding points were made in selected localities (table 1). The maximum half current electrode spacing (AB/2m). was varied from 350 meters to 500 meters depending on the complexities in geology and availability of space. For each location, 3 soundings, using Schlumberger electrode array were made on the basis of which Government boreholes drilled by the Cross River State Basin, and Rural Development Authority were sited. All the interpreted curves with distinctive similarities were selected and grouped in accordance with the three sub-classified zones (Figure 3) made for the entire area. A representative curve from amongst the three (Figures 3-6) (a-c respectively) so selected from the respective zones A,B,C and an unclassified transitional zone (Fig 6a-c respectively) were then displayed and interpreted.

Drilled cuttings from the boreholes drilled during this project period were collected and the electrical logging of the wells (where applicable) was made. The combination of lithofacies characteristics and electric log responses coupled

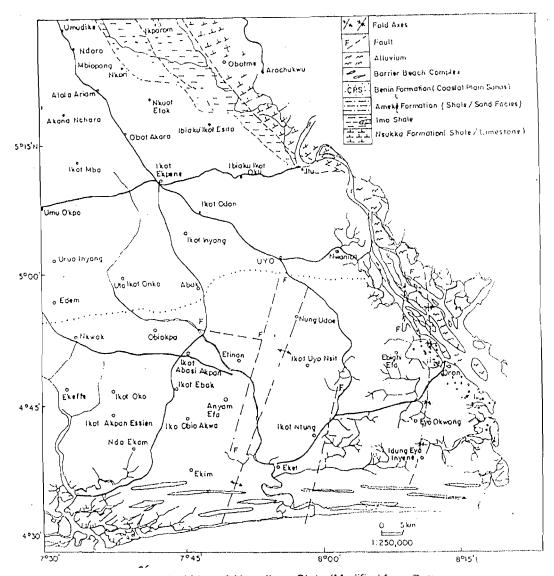

Figure 2 Geological Map of Akwa Ibom State (Modified from Petters, 1989)

with the surface geophysical and geological interpretation provided adequate information on the groundwater potentials of the study area. Variations in elevation were documented for each location with the help of a ground positioning system (GPS). Computer modeling programme (Zoddy) was used for the interpretation of the VES data for proper delineation of the various aquiferous units existing in the study area. Delineated aquifers were then correlated along strike in terms of both thickness and depth of occurrence in all the localities in a similar manner in which the well cuttings and electric log

responses (from wells that were available for logging) were done.

DISCUSSION OF RESULTS

Figure 3-6 (a-c respectively) are the representative curves and selected from the stack of Nine sounding points from each of the sectional zones of extreme south (coastal region), central and the northern axis. Table 3 gives the interpretation made from the curves. Also, figure 7 is a typical (representative) log display for one of the representative wells from sector B.

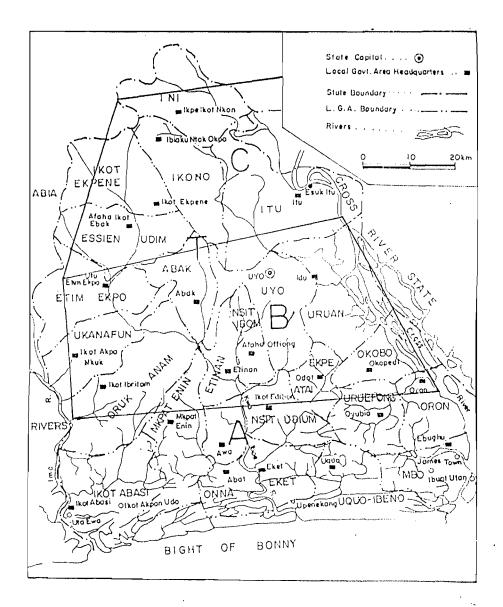

Figure 2b Map of Akwa Ibom State showing the Local Government Areas sectional subdivisions. (Modified from Petters, 1989)

Interpretation made on the basis of figures 3-11 have revealed the existence of 3 resistive earth layers in all three sectors. Results show that layers 2 and 3 in the localities within sectors A and B (figure 3) with resistivities of 377 and 1952 ohm meters, 323 and 1350 ohm meters respectively in section make up the main aquiferous units. These aquifers exist between 52 and 76 meters depth with insignificant variations in their depth of occurrences within the sector where unconsolidated sands with minor clays form the main lithologic units. The mean elevation

value is no more than 20.7m. In section B, these aquifers occurs between 65 and 92 meters depth. Here the thickness of clay units and their abundance appear quite significant. On the basis of this, all the wells drilled within sector B were terminated between 100 and 110 metes whereas those of sector A were terminated between 82 and 87 meters. The apparent variations in the depths of occurrence of these aquifers show clearly that there is a slight dip variation in the formations of the area. This element of dip had earlier been reported and estimated to between 6

and 10° by Esu et al (1999). Drilled cuttings from wells within sectors A and B (tables 3 and 4) show a good agreement except for the frequencies of clay occurrences. Topographically, zone B rests on a higher ground based on the mean GPS reading of 87ft (26.5m).

In zone C, which comprises Ibiono Ibom. Ikono, Itu and the eastern part of Ikot Ekpene Local Government Areas, the results are unexpectedly different from those of zone A and B. Table 5, figures 3 and 6 which are the interpreted VES data of zone C do not reveal the occurrence of a shallow aquifers at all giving the resolving power of Terrameter SAS 300 used in the surveys. Villages within this sector clearly sit on a relatively higher elevated ground following a GPS reading of 167-186ft. Geologic mapping in the area reveals dominant occurrence of

compacted clays, belonging to the Imo shales of Murat (1972) with minor sand stringers in places. Shales are known to have high porosities and very low permeabilities (Rider, 1986, North, 1990) and so generally inhibit free movement of ground water. Their resistivities which should at least give a fair correlation with those of zones A and B which defines the first and second aquifers are rather low (20-44 Ω m) in most of the sounding points. It is therefore apparent that the aquifer units which stretches from zone A through B are either pinched-out getting to zone C or are rather dipping in the region, beyond resolvable depth. This may in parts lend credence to the considerable number of boreholes failures in this part of Akwa Ibom State. On the other hand, shallow unconfined aquifers exist at depth slightly greater 20m. Owing to the fact that saturated

aquiferous units are apparent based on interpretations made from figure 6, it could be inferred that the areas within Ikot Obio Okon are in a transition zone which straddles the Tertairy-

Cretaceous hydrostratigraphic units of Esu et al (1999). Hydrogeological potentials for communities within this region, even though classified into zone C subsector (southernmost

section) is expected to be high even though drilling into slightly relatively higher depth would necessarily have to be done owing to topographic variations in comparison with those of zones A and B.

CONCLUSION

Aquifer distribution patterns in Akwa Ibom State are greatly influenced by geologic and topographic variations. Within the coastal regions and the hinterlands, groundwater exploitation is very feasible owing to the predominance of

saturated sands within relatively shallow depth intervals whereas up north within Ibiono Ibom and Itu Local Government Areas where topography is relatively higher together with the dominance of thick compacted clays as the main lithofacies, aquifers are lacking within considerable limit of the resolving power of Abbem Terrameter 300SAS, used in the investigation. Groundwater occurrence in this part of the study area therefore appears to favour surface water development schemes rather than the conventional borehole project involving particularly handpump wells.

ACKNOWLEDGEMENTS

The authors express their gratitude to the Cross River State Basin and Rural Development Authority for approving this research to its borehole drilling contractors. Mr. Gideon Akpan and Ubong Victor who supplied the well cuttings/litholog sections of some of the drilled wells are greatly indebted to. We are also thankful to Messrs Aniedi Ukpong and Aniekan Eshiet for their assistance in the field.
