### SUMMARY

**Introduction:** The burden of MDR-TB is unknown in areas that do not have drug susceptibility testing (DST), but its frequency is expected to be higher in previously treated cases. Where DST is not available the WHO recommended standardized retreatment (Category II) regimen is given to previously treated TB patients

**Objective:** To evaluate the frequency and pattern of drug resistance of *Mycobacterium tuberculosis* isolated from patients with chronic smear positive pulmonary tuberculosis.

**Method:** We conducted a retrospective review of mycobacterial cultures and drug susceptibility testing (DST) performed on sputum samples collected, between January 2005 and September 2006, from 40 patients with pulmonary TB who had failed at least one standard retreatment regimen. Clinical data was extracted from patients' case notes.

**Results:** *M. tuberculosis* was recovered from 28 (70%) of the 40 patients. Of the 28 culture positive cases, 10 (36%) had resistance to at least rifampicin and isoniazid (multi-drug resistant TB), 22 (79%) isolates had resistance to streptomycin and 13 (46%) to ethambutol. Of the patients with a positive culture, only one (3.6%) had a fully susceptible organism. Of the 10 patients with MDR TB, 7 had received two or more retreatment courses.

**Conclusion:** The frequency of drug resistant TB was high among patients who failed at least one course of category II therapy. Effective combination regimens based on DST is necessary in patients who remain smear positive on the standardized retreatment regimen.

**Keywords:** drug-resistance, MDR, chronic TB, retreatment regimen.

### INTRODUCTION

Drug resistant tuberculosis (TB), particularly multidrug resistant (MDR) represents a major global public health

problem. Several studies have found that MDR TB is associated with a higher risk of treatment failure and death.<sup>1-6</sup> Based on data from 184 countries, it was estimated that 4.3% of all reported TB cases and 18.5% of previously treated cases in 2004 were MDR.<sup>7</sup> In areas where drug susceptibility testing (DST) is not available, a standardized retreatment (category II) regimen is recommended for previously treated TB patients.<sup>8</sup> This regimen consists of streptomycin (S), rifampicin (R), isoniazid (I), pyrazinamide and ethambutol (E) for two months, followed by one month of the same drugs except for streptomycin and then five months of rifampicin, isoniazid, and ethambutol (2SRHZE-1RHZE-5HRE).

Countries in South America and Sub-Saharan Africa that have well organized DOTS programmes have a prevalence of chronic TB (defined as a case that remains sputum positive at the end of a supervised standard retreatment regimen) is estimated at < 2%.<sup>8,9</sup> Adherent patients who remain smear positive at the end of the standard retreatment regimen are likely to have MDR TB and would need second-line drugs. In 2006 Green Light Committee (GLC) projects treated less than 5% of MDR-TB cases that emerged world-wide, and by the end of 2007 only 51 countries had been provided with second-line anti-TB drugs through the GLC.<sup>10</sup>

In areas that do not have second-line drugs, the main option available to persons who have failed a standard treatment regimen is often a repeat of the same Category II regimen. This suboptimal approach to the management of chronic smear positive cases poses a significant transmission risk of resistant TB to close contacts and health care workers who provide care for these patients.

Repeating Category II treatment after failure of a supervised retreatment regimen is likely to increase the

degree and spectrum of drug resistance to first line drugs.

Patients who had failed at least one previous treatment (the total number of 'retreatment cases') in Ghana in 2006 were 526 (about 5% of all TB patients), of which the majority were due to relapse/failure and about 10% of these were defaulters (National TB Program reports). There were 56 patients on retreatment at the Chest Clinic in 2005 and 2006, and chronic TB cases would be a small proportion of this. Outcomes in these patients from Chest Clinic were; about 50% cure, 12.5 % failure/relapse, 12.5% default and 25% mortality.

The Chest Clinic laboratory in Korle Bu Teaching Hospital, the tertiary referral hospital for southern Ghana, was the only laboratory under the Ghana Health Service/Ministry of Health performing mycobacterial cultures in the southern half of Ghana in that period. Sufficient information had been sent out by the National TB Program on the availability of the mycobacterial culture service and most DOTS centres in the region referred their chronic patients to Chest clinic for this reason. In this review, we evaluated the frequency and pattern of drug resistance of *Mycobacterium tuberculosis* isolated from patients with chronic smear positive pulmonary tuberculosis, who remained smear and culture positive for acid-fast bacilli (AFB) at the end of one or more courses of standard retreatment (Category II) therapy.

## METHOD

The culture results of all chronic TB cases (had failed at least one retreatment course) referred to the Korle-Bu Teaching Hospital Chest Clinic laboratory, representing a sample of chronic cases from the south of Ghana were reviewed. As the number of chronic cases in the country was small all patients who fitted the definition of chronic TB were included in the study. A retrospective review was carried out over a period of 21 months, from January 2005 to September 2006, of consecutive patients referred to the Chest Clinic laboratory who had a positive sputum smear test, having failed at least one retreatment course. Patients' case notes were retrieved for information on number of retreatments, HIV status and outcomes. HIV screening, not available in the Chest Clinic, was done at the Public Health Reference Laboratory in Korle Bu.

Counselling and HIV screening of TB patients was selective, based on clinical suspicion of HIV and patients' willingness to be tested. Sputum samples from 33 consecutive patients were received, with six of the 33 patients re-entered into the study as their sputums were re-cultured within the study period, after failing further retreatment courses. Two samples, one spot and an early morning sample, were pooled and pre-

treated with 1% Cetylpyridinium Chloride (CPC) to inhibit the growth of fungi and other bacteria present. All samples were smear positive by Zeihl-Neelsen staining for AFB. Liquefaction and decontamination was carried out with the modified Petroff method.<sup>11</sup> The specimen was inoculated onto 3 Lowenstein-Jensen (LJ) slopes containing 0.5% pyruvate, glycerol and PNB (p-nitrobenzoic acid 500 mg/l), and were incubated at 37 °C for up to 8 weeks. *Mycobacterium tuberculosis* was confirmed by colony morphology, absence of pigment and failure to grow in PNB. Mycobacteria-other than TB (MOTT) were identified by rapid growth within 7 days and growth in PNB.<sup>12</sup>

Positive *M. tuberculosis* cultures were sub-cultured, and susceptibility testing to isoniazid, rifampicin, streptomycin and ethambutol was performed by the simplified proportion method.<sup>13</sup> The critical concentrations of the drugs were as follows: isoniazid 0.2 mg/l, rifampicin 40 mg/l, streptomycin 4.0 mg/l, and ethambutol 2.0 mg/l. The threshold proportion for resistance was 1% for all drugs. A standard H37Rv strain of known resistance to the drugs tested was used as controls in each batch of tests.

## RESULTS

Forty smear positive sputum samples were cultured of which 28 (70.0%) grew *M. tuberculosis*, 8 (20%) showed no bacterial growth, 3 had fungal contamination and one grew MOTT (a fast grower). The median age for all patients was 38.8 years with ages ranging between 9 and 75 years. Majority (71.4%) were male patients and were in the productive age group 25 to 64 years. The characteristics of the 28 patients with positive culture are shown in Table 1.

**Table 1** Demographic characteristics of 28 culture positive chronic TB patients

CHARACTERISTIC	
<b>Age (yrs)</b>	
Mean age	39.5 (SD 15.5)
Median	38
<b>Gender</b>	<b>Frequency (n)</b>
Male	20
Female	8
<b>Referral site</b>	
Chest Clinic & Accra	22
Other	6
<b>HIV status</b>	
Positive	3
Negative	7
Not Done	12
Not Available	6

**Table 2** Frequency of drug resistance among 28 culture positive chronic TB patients

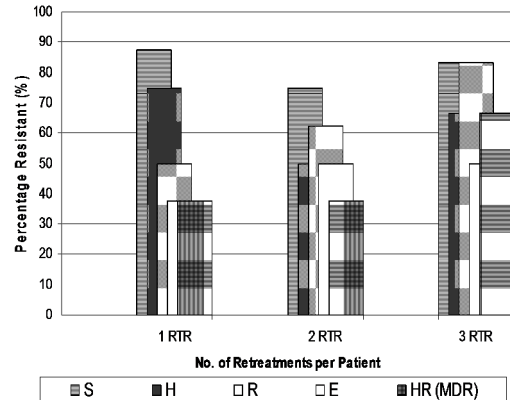

RESISTANCE PATTERN	Number	Frequency
<b>Streptomycin</b>	22	78.57%
<b>MDR (H+R)</b>	10	35.71%
<b>MDR + S</b>	7	25.00%
<b>MDR + E</b>	6	21.43%
<b>Panresistant (to SHR&amp;E)</b>	5	17.86%
<b>Ethambutol</b>	13	46.43%
<b>H alone</b>	6	21.43%
<b>R alone</b>	5	17.86%
<b>Pansensitive</b>	1	3.57%
<b>Total Resistant TB strains</b>	28	

Majority of patients were being managed at Chest Clinic, 3 were from other hospitals and clinics in Accra. Six whose records could not be traced were not Chest Clinic patients and had had cultures requested from DOTS centres in Tema and the Central Region, with one from the Ashanti Region.

Data obtained from 22 case notes showed that 6 patients had relapsed after being declared cured, 11 were failures of one or more retreatments, and 8 had a history of default, 3 being recurrent defaulters. The mean number of treatment courses they had had was 2.9, majority having had 2 or more retreatment courses. Twelve patients had not had their HIV status determined, 3 others were HIV positive and 7 HIV negative.

The results of DST are shown in Table 2. Of the 28 patients, 10 (36%) had MDR-TB, 6 (21%) had isonia-

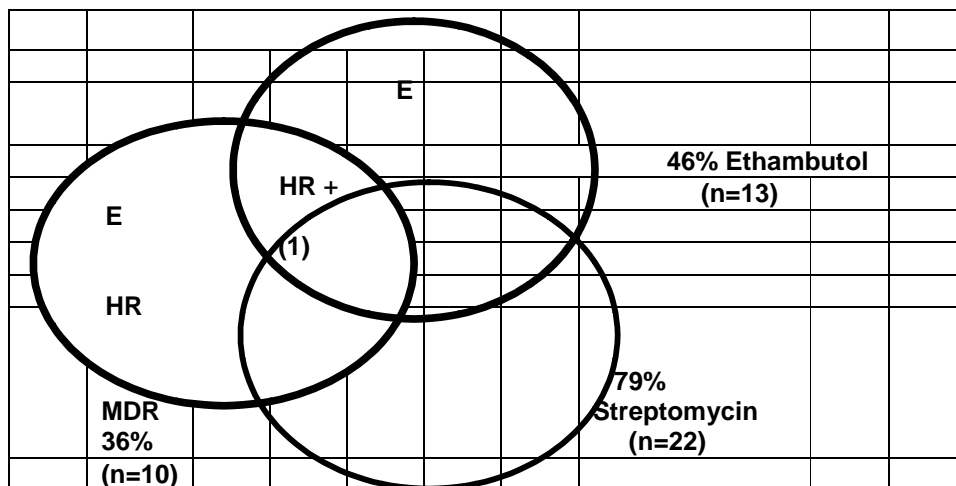

zid mono resistance and 5 (18%) had rifampicin mono resistance.

**Figure 2** Frequency of Drug Resistant- and MDR- TB in relation to number of retreatment (RTR) regimens

Overall, 79% had resistance to streptomycin, 18% had resistance to all four drugs and only one patient (3.6%) had an isolate susceptible to all 4 drugs. The prevalence of mono- and multiple-drug resistance patterns are shown in a Venn diagram (Figure 1).

Four out of 8 defaulters (50%) and 4 out of 6 with relapse-after-cure (66.6%) had MDR-TB. The proportions with mono- or multi-drug resistance in relation to the number of retreatments a patient had showed an increasing trend for rifampicin resistance and MDR, though significance could not be determined because of insufficient patient numbers (Figure 2).

**Figure 1** Pattern of Drug Resistance among 28 culture positive patients

## DISCUSSION

Tuberculosis had a world-wide incidence of 9 million people in 2006, and nearly 1.7 million people die every year from TB.<sup>8, 14</sup> Combination therapy with effective anti-tuberculosis agents is intended to improve cure rates and prevent the emergence of drug resistance. Resistance to the antituberculosis drugs is being recognized more and more as their effectiveness is subverted by poor adherence, inadequate dosing and prescription of incorrect regimens, effectively exposing organisms to monotherapy.<sup>15</sup> As developing countries acquire the expertise and the resources required to diagnose it resistant tuberculosis is being recognized more and more.

While a few drug resistance surveys have been carried out on primary TB isolates from treatment-naïve patients in Ghana, only one has studied previously treated patients. Newman MJ et al. in a previous survey of chronic TB patients in this teaching hospital reported a high level of resistance among 18 cultured isolates, with 15 (83%) showing resistance to at least two first-line anti-tuberculosis drugs.<sup>16</sup> Thirty-three percent (33%) were MDR which was similar to our review, however only 3.6% in our review were pan-sensitive to all drugs, compared with 16.7% in Newman's study, who were likely to respond to further first-line treatment. A well performing DOTS program is the best prevention against chronic disease and MDR-TB. In developing countries that have had a well applied DOTS strategy for several years, chronic cases represent less than 2% of the total smear-positive pulmonary TB cases.<sup>9,10</sup>

In a Peruvian study on mycobacterial culture and DST of pulmonary TB cases 18% of cases were MDR-TB, which accounted for 71% of deaths in both HIV positive and negative patients.<sup>3</sup> High levels of drug resistance among our chronic TB patients represents a risk for likely transmission of resistant strains to susceptible persons in the community as well as an increased mortality on standard drug therapy. A 2000-2004 survey of primary anti-TB drug resistance in Ghana on 2,064 isolates, reported then a high level of initial Streptomycin resistance of 23% in treatment-naïve patients.<sup>17</sup> The even higher prevalence of resistance to streptomycin in the present study (79%) means the recommended WHO retreatment regimen which is routinely given in the absence of DST will not be effective and may even create greater resistance to the essential drugs in use as it fails to add on any effective new drug to the Category I regimen. Among the 28 positive cultures drug resistant TB was present in all groups irrespective of whether they had had one, two or three retreatments. This was particularly so with streptomycin and isoniazid, while rifampicin and MDR resistance appeared to be more common in patients

who had completed three retreatments. We could not establish the significance of this trend given the small numbers of patients studied.

However the observed trend is what one would expect from the natural history of resistance development,<sup>15</sup> and has been demonstrated in a large cohort in Uganda.<sup>18</sup> Some authors have reported that even in the settings of moderate rates of MDR-TB, DOTS using only first-line drugs can be effective and reduce the transmission of both drug-susceptible and drug-resistant TB,<sup>2</sup> but others have found DOTS alone to be inadequate in patients with drug-resistant TB.<sup>1,14,19</sup> Urgent consideration is needed for the use of a standardized Category IV regimen combining effective first line drugs with selected second line drugs (including an injectable) for MDR, present in over a third of our chronic TB patients.

This has been feasible in other resource-limited countries with an efficient NTP, and has been demonstrated to be cost effective in Peru.<sup>9, 20</sup> A major limitation of this study is the small number of chronic TB cases included in this report. Thus, the results should be interpreted with caution. This was a new laboratory service and selection bias could have occurred as some practitioners may not have been aware of the availability of mycobacterial culture or just did not have their chronic patients' sputum cultured in spite of repeated failures. The results of this review suggest that more studies on *M. tuberculosis* resistance are required, which will give support to the strengthening of the National TB Program, for application to the Green Light Committee for second line drugs.
