Abstract: Butterflies may be specialists, generalists, or somewhere in between. In this paper, we propose a method for defining various categories of specialism, test the robustness of the method, and allocate all South African butterfly species to a category. The results are then evaluated and discussed.

Key words: Eurytype, generalist, mesotope, South Africa, specialist, stenotope.

Peer reviewed

INTRODUCTION

Generalist species (eurytopes) tolerate a wide range of habitats and ecological conditions. Specialist species (stenotopes) on the other hand, tolerate only a restricted range of habitats and ecological conditions. Extreme eurytopic butterfly species would be expected to occur in nearly all types of habitats, have an open population structure (be vagile and solitary), utilise a great variety of larval resources (while not needing specialised larval resources), have large geographical ranges, and be multivoltine. In contrast, extreme stenotopic species would be expected to occur in a single niche habitat, have a closed population structure (be sedentary and colonial), utilise very limited (and often specialised) larval resources, have very small geographical ranges, and be univoltine or bivoltine. Most species are neither specialist or generalists, and we have developed a term “mesotope” for this category.

The South African butterfly fauna is relatively large (about 665 described species), contains both extreme eurytopes and extreme stenotopes and is well studied when compared to the butterflies in the rest of the Afrotropical Region (Pringle *et al.*, 1994; Woodhall, 2020; Williams, 2023). In this paper each species is scored based on ecological parameters noted above to obtain a eurytopic-stenotopic index (ESI).

METHODS AND MATERIALS

Data on habitats, population structure, adult behaviours, larval food, ant associations, geographical range and voltinism were extracted from *Afrotropical Butterflies*, a comprehensive, continuously updated resource hosted on the website of the Lepidopterists' Society of Africa (<https://metamorphosis.org.za/?p=articles&s=atb>).

We use six ecological variables to determine the ESI of South African butterflies. A list of the variables, and the scores chosen are as follows:

- 1) Habitat.
Five biomes (simplified from Mucina & Rutherford, 2006) were considered: Forest, Savanna, Grassland, Karoo and Fynbos. Species were allocated between 1 and 5 points; one point for each biome in which they are found.
- 2) Population structure.
Two behaviors were considered: Vagile and solitary (3 points) or, Sedentary and colonial (0 points).
- 3) Larval food.
Phytophagous species.
 - Hostplant unknown or 1 plant genus only (1 point)
 - 2-5 plant genera (2 points)
 - 6-10 plant genera (3 points)
 - 11-15 plant genera (4 points)
 - 16-20 plant genera (5 points)
 - 21-25 plant genera (6 points)
 - >25 plant genera (7 points).Homopterophagous species.
 - 1 family of homopterans (1 point)
 - 1-4 families of homopterans (3 points)
 - >4 families of homopterans (7 points)Phytopredacious or predacious (on ant brood) (1 point).
- 4) Ant association.
 - Not ant dependent (3 points) or,
 - Obligate myrmecophiles (0 points).
- 5) Geographical range.
 - One province in South Africa (or in Lesotho only) (1 point)
 - Endemic to South Africa but >1 province (2 points)
 - 2-5 countries (3 points)

- 6 and more countries (but not sub-Saharan) (4 points)
 - Sub-Saharan (5 points)
 - Sub-Saharan, plus Arabia or Madagascar (6 points)
 - Sub-Saharan, plus Madagascar and Arabia (7 points)
 - Sub-Saharan, plus Madagascar, Arabia and extending beyond the Afrotropical region (8 points).
- 6) Voltinism.
- Multivoltine (3 points) or,
 - Univoltine/bivoltine (0 points).

The scored ESIs thus range from a minimum of 3 points (single biome [1 point]; sedentary and colonial [0 points]; phytopredacious or predaceous (on ant brood) [1 point]; obligate myrmecophile [0 points]; one province in South Africa (or in Lesotho only) [1 point]); univoltine or bivoltine [0 points], to a maximum of 29 points (all biomes [5 points]; vagile and solitary [3 points]; utilizing more than 25 plant genera or more than 4 homopteran families as larval food [7 points]); not ant dependent [3 points]; sub-Saharan, plus Madagascar, Arabia and extending beyond the Afrotropical region [8 points]; multivoltine [3 points]).

Species were classified as extreme stenotopes (3-5 points), semi-stenotopes (6-12 points), mesotopes (13-19 points), semi-eurytopes (20-26 points), or extreme eurytopes (27-29 points).

The categories are colour coded as indicated in Fig. 1.

Code	ESI Category	Score	Total species	Percentage
1	Extreme stenotopes	3-5	157	23,5%
2	Semi-stenotopes	6-12	113	16,9%
3	Mesotopes	13-19	332	49,7%
4	Semi-eurytopes	20-26	56	8,4%
5	Extreme eurytopes	27-29	7	1,0%
Et	Extinct		2	0,3%
Ec	Exotic		1	0,1%
				668

Figure 1 – Proportion of South African butterfly species by ESI Category.

While the bracketing figures were retrospectively adjusted slightly to suit the geometry of the resulting ESI graph (Fig. 2), the scores, and the weighting of each category, are arbitrary. To test the robustness of the ESI categories for individual species, twelve tests were undertaken, as follows:

1. The scores for “Habitat” were doubled and the ESI scores were adjusted to match (as closely as possible) the relevant percentages in Fig. 1. Each species that consequently moved to another category lost one point in a “reliability” score. The above process was repeated for “Population structure”, “Larval food”, “Ant

association”, “Range” and “Voltinism” (6 tests in total).

2. A similar series of six tests were repeated, but in this case, instead of doubling the score for each criterion, the scores were successively deleted. As above, the ESI scores were adjusted to match (as closely as possible) the relevant species totals in Fig. 1, and each species that consequently moved to another category lost one point in a “reliability” score.

The final score - a maximum of 13 (12 tests, plus the initial result) and a minimum of 1 (the original entry) – was divided by the total number of results (13) to form a percentage. This “Reliability Index” is included in Table 1. It can be seen from the resulting Reliability Index scores, that the allocation of a species to one of the ESI categories is not greatly affected by either doubling the score for a single ecological variable, or omitting an ecological variable altogether.

RESULTS

The eurytopic-stenotopic indices (ESIs) for the South African butterfly species are given in Table 1. The distribution of species within the eurytopic-stenotopic spectrum, and within butterfly families, is summarised in Table 2. The relevant data extracted from the South African Lepidoptera Conservation Assessment (SALCA) report is summarised in Table 3.

The following graph (Fig. 2) is a plot of the ESI score against the number of species that have that score (red line). The spikes in the curve are a result of mathematical rather than biological discontinuities, so a smoothed “best fit” curve was produced, by trial and error, to model the ESI distribution (black line).

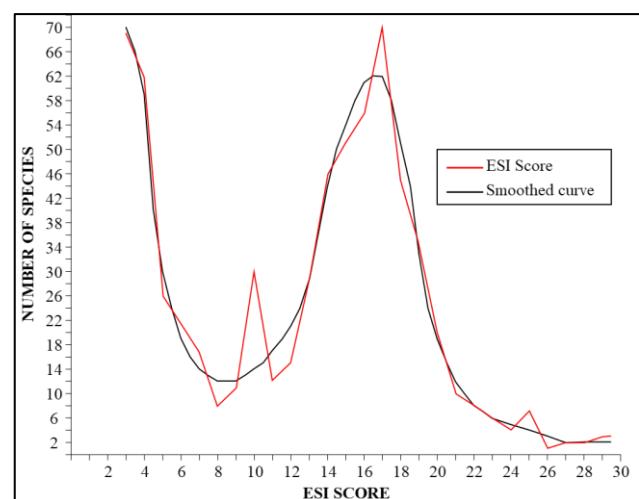

Figure 2 – Number of South African butterfly species by ESI score.

The graph on the next page (Fig. 3) takes the “smoothed” ESI curve (above) and indicates the various ESI categories.

The shape of the curve for mesotopes and eurytopes strongly resembles a normal probability distribution, and this is illustrated in Fig. 4 (below), which shows the ESI curve overlaid on a generic histogram.

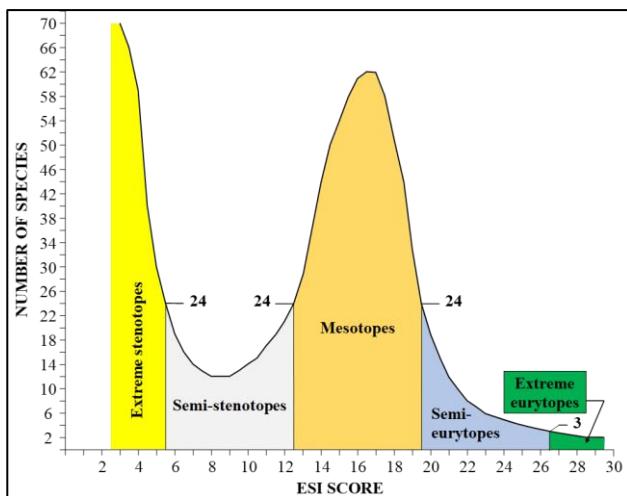

Figure 3 – Number of South African butterfly species by ESI category.

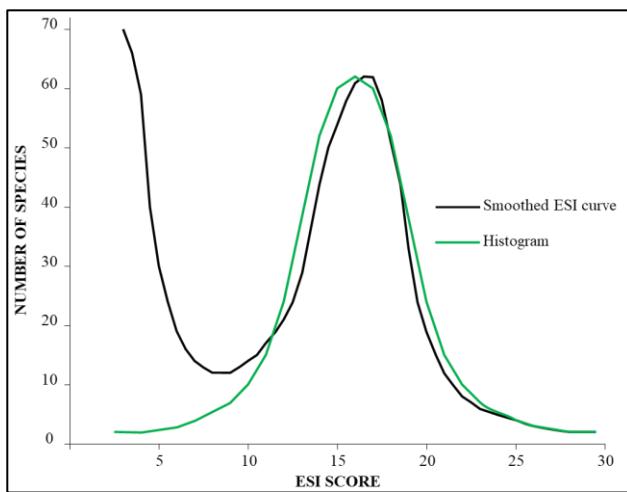

Figure 4 – Smoothed ESI curve compared to generic histogram.

It might be expected that the degree of specialisation in butterflies would follow a normal probability distribution, so that extreme specialists and extreme generalists would occupy the tails of the curve and most species would fit somewhere in between.

For mesotopes and eurytopes this seems to be the case. A feature of the graph, however, is the large number of specialist South African species. The number of species with ESI scores that exceed the average value for mesotopes (greater than 16) is 269. If the ESI curve was symmetrical about the mesotope mean, we would expect to

have double this number, 538 species in South Africa. The extent to which this number is exceeded (120 species or 22.3%) reflects the overrepresentation of stenotopes and semi-stenotopes in South Africa.

CONCLUSIONS

Butterflies may be categorised as being, to varying degrees, specialists or generalists. We present a rational method of calculating the level of specialisation of a species and allocating it to one of five groups: extreme specialists (stenotopes); moderate specialists (semi-stenotopes); average (mesotopes); moderate generalists (semi-eurytopes) and extreme generalists (eurytopes).

Specialist South African species (stenotopes and semi-stenotopes) constitute 270 species (40%), which is a far higher percentage than for species occupying the generalist end of the spectrum. The generalists (eurytopes and semi-eurytopes) account for 63 species (10%).

It appears that being a specialist (stenotope) presents an evolutionary advantage as far as the creation of new species is concerned. The price to be paid for this is that of the 86 South African butterfly species listed as being of conservation concern (Table 3), almost 90% are either stenotopes or semi-stenotopes.
