Abstract

Computer-assisted semen analysis (CASA) is an automated and objective method of evaluating structural (e.g. morphology) and functional sperm parameters (e.g. motility and hyperactivation). Sperm hyperactivation is essential for successful fertilization and is thus an important aspect in determining the fertility potential of a male. In the current study, CASA was used for standard semen analysis and for comparison of the ability of phosphate buffered saline (PBS), BO sperm wash (10 mM caffeine), 4% lignocaine, and 5 mM procaine hydrochloride to induce hyperactivation in Tankwa goat spermatozoa. Twenty-nine ejaculates were collected from randomly selected male goats by electroejaculation. Although none of the four media affected percentage total sperm motility, lignocaine caused a significant decrease ($P > 0.05$) in percentage progressive motility. Exposure to procaine resulted in an increase in swimming speed ($P \leq 0.05$) and star-spin motility tracks, which are typical of sperm hyperactivation. Using PBS and procaine motility data from individually selected spermatozoa, receiver operator characteristic curves were constructed to distinguish the kinematic parameters employed as cut-off values for sperm hyperactivation. PBS and BO sperm wash did not induce hyperactivation ($0.1 \pm 0.2\%$ and $0.04 \pm 0.2\%$ respectively), while lignocaine induced little hyperactivation ($3.4 \pm 3.0\%$) and procaine hydrochloride had the highest percentage hyperactivation ($25.3 \pm 13.6\%$). The large variation in hyperactivation (0–54.5%) may reflect inter-individual differences in sperm quality among these males. This study indicated procaine hydrochloride was the most promising hyperactivation-inducing medium for Tankwa goat spermatozoa and should be considered for similar assessments in other animal species.

Keywords: computer-aided sperm analysis, procaine hydrochloride, sperm kinematics, sperm morphometry, sperm motility

Introduction

Tankwa goats originated from an isolated population of feral goats in the south-western region of the arid Karoo district, mainly Tankwa Karoo National Park (Northern Cape, South Africa), where they are thought to have been roaming free for more than 80 years without human interference. At least two studies have shown that the Tankwa goat is closely related to other indigenous goat breeds (e.g. Boer and South African village goats) and has similar genetic diversity (Kotze *et al.*, 2014; Ncube *et al.*, 2016). Kotze *et al.* (2014) compared the Tankwa goat with commercial breeds such as Boer, Angora, and Saanen goats, and concluded that the Tankwa goat is a unique genetic resource that needs to be managed optimally. An understanding of their reproductive biology could add valuable information to conservation strategies and the breeding potential of Tankwa goats.

Semen and sperm quality assessments are important in predicting the fertility potential of males and are based primarily on the manual evaluation of conventional parameters such as semen volume, sperm motility, concentration, morphology, viability, and acrosome integrity (Verstegen *et al.*, 2002). During the past

three decades several commercial computer-aided sperm analysis (CASA) systems have been developed, primarily to promote standardized and quantitative evaluation of semen samples. CASA allows for faster, accurate and more detailed results and eliminates the subjective biases that are inherent in manual semen analysis (Coetzee *et al.*, 2001; Van der Horst *et al.*, 2018a).

Mammalian spermatozoa cannot fertilize oocytes immediately after ejaculation. A series of changes must occur in the physical and chemical properties of the sperm head and the tail plasma membrane before they are able to penetrate the zona pellucida and bind to the oocyte (Hunter, 2012; Gervasi & Visconti, 2016). Collectively these changes are termed 'capacitation' and are associated with both hyperactivated motility and the spermatozoon's ability to undergo the acrosome reaction (Visconti *et al.*, 2011; Puga Molina *et al.*, 2018).

Spermatozoa generally have two phases of motility, namely active and hyperactivated. Active motility occurs in a fresh ejaculate and displays a symmetrical low-amplitude waveform, which assists spermatozoa to swim in a straight line (Henkel *et al.*, 2005). During sperm hyperactivation, the flagellar beat pattern is characterized by wide amplitude, large lateral movements of the head and the flagellum, which is coupled with fast, non-progressive motility, which is also referred to as the 'star-spin' movement (Yanagimachi, 1994; Ho & Suarez, 2001). Hyperactivation is thought to provide strong thrusting power to the spermatozoa while passing through the viscoelastic female reproductive tract and the egg investments, particularly the zona pellucida (Ardon *et al.*, 2016; Suarez & Wu, 2017). The crucial signal for the induction of hyperactivation appears to be an increase in intracellular levels of the calcium ion (Ca^{2+}) (Strünker *et al.*, 2011; Sumigama *et al.*, 2015), through the opening of pH-sensitive cation channels of sperm (CatSper) in the flagellar plasma membrane (Alasmari *et al.*, 2013; Tamburrino *et al.*, 2015) and the release of Ca^{2+} from stores in the sperm neck and midpiece region (Ho & Suarez, 2003; Costello *et al.*, 2009).

Assessment of hyperactivation can serve as a biological marker to evaluate the functional capabilities and fertility potential of spermatozoa because of its association with fertilization success and live birth outcomes in humans and domesticated animal species (McPartlin *et al.*, 2009; Alasmari *et al.*, 2013; Williams *et al.*, 2015). CASA has been used to establish the percentage hyperactive flagellar movement according to species-specific kinematic cut-off values set by the user for hyperactivation (Mortimer *et al.*, 2015). Several chemicals have been used to induce and measure hyperactivation in vitro objectively, such as progesterone (Strünker *et al.*, 2011), caffeine (Colás *et al.*, 2010), procaine hydrochloride (McPartlin *et al.*, 2009) and 4-aminopyridine (Bedu-Addo *et al.*, 2008).

Except for a study on the seminal plasma constituents of Tankwa goats (Ramukhithi *et al.*, 2018), there is not sufficient information about the reproductive biology of these goats to select males for future breeding and smallholder farming. The purpose of this study was to provide a more detailed investigation of male fertility by employing objective and novel techniques to evaluate the semen characteristics and sperm functionality of Tankwa goats. Computer-assisted semen analysis was used to quantify semen parameters for Tankwa goats and compare the abilities of four media and chemicals to induce sperm hyperactivation. Because kinematic parameter cut-off values for hyperactivation were not available for goat spermatozoa, an imperative objective was to determine and subsequently apply such values to Tankwa goat spermatozoa and assess their fertility potential.

Materials and methods

All procedures were performed in agreement with and approved by the Animal Ethics Committees of the University of the Western Cape (Project number AR17/5/29) and the Research Ethics and Scientific Committee of the National Zoological Gardens (Project number NZG/RES/P17/34).

Randomly selected and sexually mature male Tankwa goats from Carnarvon Research Station (Northern Cape Department of Agriculture, Land Reform and Rural Development) were used for this study. The research station is located at 30° 95' S and 22° 13' E in Carnarvon, South Africa, and is situated at an altitude of 1234 m above sea level. The free-roaming male goats were held in two large permanent camps (total size of 1000 ha) together with females (not limiting ejaculation prior to sampling) and had free access to water and natural vegetation. The research station is located in the Nama-Karoo Biome and the vegetation type is classified as Western Upper Karoo (NKu 1), consisting mainly of a mixture of small-leaved shrubs, shrubby succulents, drought-resistant grasses and few tree species (Mucina & Rutherford, 2006).

Semen samples ($n = 29$) were collected during the summer season (February) over a three-hour period in the early morning. Males were restrained in a recumbent sitting position, and samples were collected into sterile pre-warmed (37 °C) 50 ml polypropylene tubes. Semen was produced by means of peri-prostatic electro-stimulation using an Etoro 3 rectal probe electro-ejaculator (Electronic Research Group, Midrand, South Africa), according to a method adapted from Malejane *et al.* (2014). Electrical stimulation (5-15 V, 500 mA) was applied at intervals of three to five seconds, and alternated with rest periods of three to five seconds, for a maximum of six times. During stimulations, the current was increased gradually until an

ejaculate was obtained within 1–2 minutes (Noakes *et al.*, 2009). Ejaculates were kept at 37 °C immediately after collection and for the duration of all experimental procedures.

A basic semen analysis was performed to evaluate the quantity and quality of each sample by assessing semen volume, pH, macro movement, sperm concentration, sperm motility (including percentages total motility, progressive motility, rapid-, medium- and slow-swimming spermatozoa) and sperm vitality. The swimming-speed subpopulations were determined with curvilinear velocity (VCL) cut-off values of 20<80>180 $\mu\text{m/s}$ to identify slow-, medium- and rapid-swimming spermatozoa (Maree & Van der Horst, 2013). Sperm concentration and motility were evaluated by placing 3 μl semen into a preheated (37 °C) Leja four-chamber slide (Leja Products B.V., Nieuw-Vennep, The Netherlands). Fields were randomly captured at 50 frames per second using the motility/concentration module of the sperm class analyser (SCA[®], version 6.0, 2018, Microptic S.L., Barcelona, Spain) CASA system. Additionally, a Basler Ace ACA-1300-200uc digital camera (Microptic S.L., Barcelona, Spain) was mounted on a Nikon Eclipse 50i microscope (IMP, Cape Town, South Africa), equipped with a 10x objective, using negative phase contrast optics and a heated stage (37 °C). At least two fields were captured and analysed for each semen sample, including a minimum of 200 motile spermatozoa in total.

Sperm vitality was evaluated using BrightVit[®], a nigrosin-eosin stain (Microptic SL, Barcelona, Spain). A volume of 5 μl semen was mixed with 15 μl preheated BrightVit and incubated for 30 seconds before smears were made. Mounted preparations were viewed with a x40 objective, bright field optics and a blue filter using the same microscope and camera as for motility analysis. Vitality of at least 100 spermatozoa from each semen sample was assessed with the vitality module of SCA software (version 6.0, 2018).

Sperm morphometry and morphology were assessed and quantified using SpermBlue (Microptic SL, Barcelona, Spain), a universal stain for automated sperm morphology analysis (ASMA) (Van der Horst & Maree, 2009). Stained slides were left to air dry overnight and were then mounted with a coverslip using DPX mounting medium. Sperm morphometry was assessed using a 60x objective on a Nikon Eclipse 50i microscope (IMP, Cape Town, South Africa) and a Basler Ace ACA-1300-200uc digital camera (Microptic S.L., Barcelona, Spain). Images of at least 100 spermatozoa were captured analysed with the morphology module of the SCA software (version 6.0, 2018).

Eleven sperm morphometry parameters were measured by SCA, as indicated in Table 1. Because of the lack of reference values for assessing the percentage Tankwa goat spermatozoa with normal morphology, cut-off values for normal morphology were determined as described by Van der Horst *et al.* (2018b). Minimum and maximum values for each parameter (Table 1) were derived from 90% confidence intervals to generate a Tankwa goat configuration function for evaluating normal sperm morphometry. Normal sperm head morphometry values established by Gravance *et al.* (1995) for Alpine goats fall within the current measured ranges for Tankwa goats, except for head area.

Table 1 Sperm morphometry measurements used in determining percentage normal morphology for Tankwa goat spermatozoa

| Sperm component | Measurement | Minimum | Maximum |
|-----------------|--------------------------|---------|---------|
| Head | Length, μm | 7.45 | 10.87 |
| | Width, μm | 3.50 | 5.10 |
| | Area, μm^2 | 26.30 | 51.52 |
| | Perimeter, μm | 16.67 | 23.59 |
| | Ellipticity | 1.78 | 2.53 |
| | Elongation | 0.28 | 0.43 |
| | Roughness | 0.79 | 1.75 |
| | Regularity | 0.61 | 0.97 |
| | Acrosome, % | 47 | 100 |
| | Vacuoles, % | 0 | 20 |
| Midpiece | Width, μm | 0 | 1.99 |
| | Area, μm^2 | 0 | 27.50 |

Because mammalian spermatozoa react differently to physiological media that are used to dilute and induce capacitation, it was decided to first evaluate the effect of selected media on sperm motility. Spermatozoa were exposed to four pre-warmed (37 °C) media, namely phosphate buffered saline (PBS) (control), BO sperm wash (containing 10 mM caffeine, as proposed by Brackett and Oliphant (1975)), 4% lignocaine in PBS (G. van der Horst, personal communication, 2016) and 5 mM procaine hydrochloride in PBS (McPartlin *et al.*, 2009). According to the flush technique (Boshoff *et al.*, 2018), 2 µl of each medium was used to flush 1 µl semen into the chambers of a Leja slide (Leja Products B.V., Nieuw-Venep, The Netherlands), while keeping the slide on a heated stage. Sperm motility was evaluated for each semen sample five minutes after exposure to the media. In addition to the sperm motility percentages, eight kinematic parameters were measured, namely VCL, VAP, straight-line velocity (VSL), straightness (STR) ($STR = VSL/VAP$), linearity (LIN) ($LIN = VSL/VCL$), wobble (WOB) ($WOB = VAP/VCL$), amplitude of lateral head displacement (ALH), and beat-cross frequency (BCF). The ALH parameter was measured as half the width of the VCL track and not as the full VCL wave or doubling of the riser values (risers method) as described by Mortimer (1994, 1997).

Sperm kinematic parameter cut-off values for identifying Tankwa goat spermatozoa that displayed hyperactive motility were determined with a method described by Mortimer *et al.* (2015). First, individual spermatozoa from each semen sample ($n = 290$ in total; 145 from PBS and 145 from procaine medium) were selected upon displaying typical activated linear swimming patterns after exposure to PBS or typical hyperactivated star-spin swimming patterns after exposure to procaine hydrochloride, respectively (Figure 1). Kinematic data of spermatozoa selected through such visual pattern recognition were used to construct receiver operating characteristics (ROC) curves (DeLong *et al.*, 1988) for each of the eight kinematic parameters. Only those parameters that displayed both high sensitivity and specificity (>80%) when comparing the PBS and procaine treated samples were selected as cut-offs for hyperactivation. These cut-off values were used to create a sort function for Tankwa goat sperm hyperactivation in the SCA motility module.

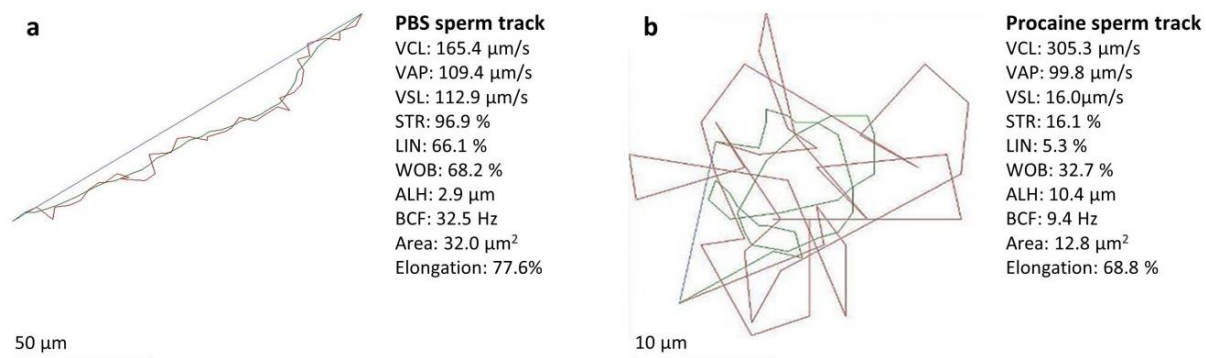

Figure 1 Typical movement patterns of individual spermatozoa captured at 50 frames per second, a) Relatively straight-swimming track after PBS incubation, and b) star-spin track after procaine hydrochloride exposure

VCL: red line, VAP: green line, VSL: blue line. VCL: curvilinear velocity, VAP: average path velocity, VSL: straight-line velocity, STR: straightness, LIN: linearity, WOB: wobble, ALH: amplitude of lateral head displacement, BCF: beat cross frequency

All the data were collected and saved as CASA files, and then transferred to MedCalc software (version 12.3.0, 2018, Mariakerke, Belgium). Levene's test for equality of variances was applied and when $P > 0.05$, one-way analysis of variance analysis (ANOVA) was performed for parametric data distributions. Significant differences ($P \leq 0.05$) indicated in the ANOVA table among groups were further analysed using the Student-Newman-Keuls test for pairwise comparisons. In subsets of data that appeared to have non-parametric data distributions, the Kruskal-Wallis test was used and, when required, the Mann-Whitney test for independent samples was applied. Correlation coefficients were also calculated between percentage sperm hyperactivation and all other semen and sperm characteristics. Data were represented as mean \pm standard deviation (SD) in the tables while $P \leq 0.05$ was considered significant.

Results and Discussion

A mean volume of 1.3 mL Tankwa goat semen was collected during electro-ejaculations, while it ranged between 0.4 mL and 2.5 mL (Table 2) for all samples. The semen contained on average 2293.7×10^6 /mL spermatozoa and a total sperm count of $29.5 \pm 8.9 \times 10^9$, with a large range between the minimum (35.2×10^6 /mL) and maximum (8540.0×10^6 /mL) concentrations. The mean semen pH was 6.0 ± 0.9 and macro-movement of spermatozoa ranged between 2 and 5 (average 4.3 ± 0.9). Spermatozoa had a total motility of $83.7 \pm 10.5\%$, of which 65.3% on average portrayed progressive motility characteristics. The three sperm subpopulations based on swimming speed included 12.8% rapid-swimming, 61.1% medium-swimming and 13.6% slow-swimming spermatozoa. Sperm vitality assessments revealed that semen contained $71.8 \pm 13.8\%$ live spermatozoa.

Morphometry measurements indicated that Tankwa goat spermatozoa had a head length of $8.5 \pm 0.2 \mu\text{m}$ and width of $4.0 \pm 0.1 \mu\text{m}$, which contributed to a head area and perimeter of $35.3 \pm 2.6 \mu\text{m}^2$ and $18.6 \pm 0.6 \mu\text{m}$, respectively (Table 3). Head elongation, ellipticity, regularity and roughness had little variation among spermatozoa. The acrosome covered on average 55.6% of the sperm head. The two midpiece morphometrics showed a mean width of $1.1 \mu\text{m}$ and a mean area of $10.9 \mu\text{m}^2$. Using the cut-off morphometric values displayed in Table 1, ASMA revealed that $62.0 \pm 26.3\%$ of Tankwa goat spermatozoa portrayed normal morphology. The values displayed in Table 1 and Table 3 are from different sperm populations.

Table 2 Semen characterization for Tankwa goat population (n = 29)

| | Mean | Standard deviation | Minimum | Maximum |
|----------------------------------------|--------|--------------------|---------|---------|
| Volume, mL | 1.3 | 0.5 | 0.4 | 2.5 |
| pH* | 6.0 | 0.9 | 5.5 | 7.5 |
| Sperm concentration, $\times 10^6$ /mL | 2293.7 | 1853.6 | 35.2 | 8540.0 |
| Total sperm count, $\times 10^9$ | 29.5 | 8.9 | 0.3 | 111.0 |
| Macro-movement | 4.3 | 0.9 | 2.0 | 5.0 |
| Total motility, % | 83.7 | 10.5 | 59.0 | 96.1 |
| Progressive motility, % | 65.3 | 13.3 | 38.9 | 85.3 |
| Rapid, % | 12.8 | 11.3 | 2.6 | 43.1 |
| Medium, % | 61.1 | 12.6 | 34.6 | 85.8 |

| Vitality, % | 71.8 | 13.8 | 39.0 | 94.0 |

*n = 5, Rapid: rapid-swimming sperm, Medium: medium-swimming sperm, Slow: slow-swimming sperm

Sperm motility percentages and the kinematic characteristics of spermatozoa exposed to the four media are displayed in Table 4. While no difference was found among the media for percentage total motility, the lignocaine-supplemented medium resulted in significantly lower percentage progressive motile spermatozoa (25.4%) compared with the other media (40.0–48.9%). Furthermore, the procaine-supplemented medium resulted in the highest average percentage of rapid-swimming spermatozoa (44.4%), whereas BO sperm wash had the lowest average for this parameter (6.2%). Exposure to the procaine medium resulted in the highest averages for VCL and ALH compared with the other three media. Procaine and lignocaine also resulted in significantly lower average VSL, STR, LIN, WOB and BCF than PBS and BO sperm wash (Figure 2). Similar differences in the sperm kinematics were found when the effect of the media on three sperm subpopulations were evaluated (Table 5). These differences in sperm kinematics resulted in distinctive swimming tracks for the four media, with more linear patterns being seen in PBS and BO wash (Figures 3a and 3b) and more irregular circular or star-spin-type patterns being seen in lignocaine and procaine (Figures 3c and 3d).

Table 3 Sperm morphometry and morphology for Tankwa goat spermatozoa (n = 7)

| | Mean | Standard deviation | Minimum | Maximum |
|--------------------------------|------|--------------------|---------|---------|
| Head length, μm | 8.5 | 0.2 | 8.4 | 8.8 |
| Head width, μm | 4.0 | 0.1 | 3.9 | 4.2 |
| Head area, μm^2 | 35.3 | 2.6 | 32.5 | 39.1 |
| Head perimeter, μm | 18.6 | 0.6 | 17.5 | 19.3 |

^{a-c} Within a row means with a common superscript did not differ at $P=0.05$

R: rapid-swimming sperm, M: medium-swimming sperm, S: slow-swimming sperm, VCL: curvilinear velocity, VSL: straight-line velocity, VAP: average path velocity, STR: straightness, LIN: linearity, WOB: wobble, ALH: amplitude of lateral head displacement, BCF: beat cross frequency

Eight receiver operating characteristic (ROC) curve analysis graphs were constructed. Almost all of the kinematic parameters displayed high sensitivity and specificity values to distinguish between straight-line and hyperactivation swimming tracks (Table 6). Only the VAP parameter had sensitivity and specificity values below 80% and was thus not regarded as being a restriction. The criterion values of the other seven kinematic parameters were used as cut-off values for Tankwa goat sperm hyperactivation (Table 6). After creating a sort function for Tankwa goats on the SCA motility module using these cut-off values, sperm hyperactivation was calculated automatically and expressed as a percentage of motile spermatozoa.

Procaine hydrochloride caused a high percentage of hyperactivation (25.3%) compared with the other three media (Table 4). It is clear from Figure 3d that procaine induced typical star-spin patterns, some of which were also detected in lignocaine (Figure 3c), but not often in PBS or BO sperm wash (Figures 3a and 3b). However, there was a large variation (0 - 54.5%) in the percentage hyperactivation induced by procaine in individual semen samples (Figure 4). Percentage sperm hyperactivation was less than 10% in three males, more than 20% in seventeen males, and more than 40% in six males.

The percentage hyperactivation induced by procaine had a significant positive relationship with semen progressive motility ($r = 0.39$, $P = 0.04$) and rapid-swimming spermatozoa ($r = 0.47$, $P = 0.02$), and VCL in PBS ($r = 0.45$, $P = 0.02$), VAP in PBS ($r = 0.40$, $P = 0.04$) and ALH in PBS ($r = 0.50$, $P = 0.01$).

Table 6 Receiver operating characteristic curve analysis and kinematic parameter restrictions for Tankwa goat hyperactivated spermatozoa

| Parameter | Sensitivity | Specificity | Restriction Setting |
|----------------------|-------------|-------------|---------------------------|
| VCL, $\mu\text{m/s}$ | 94.4 | 91.8 | $221 > \text{VCL} < 500$ |
| VSL, $\mu\text{m/s}$ | 99.3 | 98.6 | < 49.8 |
| STR, % | 100.0 | 100.0 | < 47.2 |
| LIN, % | 100.0 | 100.0 | < 15.3 |
| WOB, % | 97.2 | 97.3 | < 50.5 |
| ALH, μm | 99.3 | 100.0 | $5.3 > \text{ALH} < 15.3$ |
| BCF, Hz | 86.0 | 95.9 | < 23.8 |

VCL: curvilinear velocity, VSL: straight-line velocity, STR: straightness, LIN: linearity, WOB: wobble, ALH: amplitude of lateral head displacement, BCF: beat cross frequency

Figure 4 Induced sperm hyperactivation percentage of individual Tankwa goats with the use of phosphate buffered saline and 5 mM procaine hydrochloride ($n = 28$)

A large variation was seen in the percentage hyperactivation of individual semen samples with 17 of the samples displaying more than 20% hyperactivation
 PBS: phosphate buffered saline

While any standard semen analysis (CASA or manual) can assist in defining the quality of a semen sample, such an assessment cannot predict fertility per se (Van der Horst & Du Plessis, 2017). Two advantages of using CASA for evaluation of sperm motility and morphology are that it allows for objective detection of subtle differences among individual spermatozoa and it provides quantitative information on parameters that cannot be assessed manually (e.g. kinematics and subpopulations). Evaluation of sperm subpopulations, such as percentage sperm mucous penetration and hyperactivation, is highly recommended and will determine whether an ejaculate contains sufficient functional spermatozoa to potentially reach and fertilize the oocyte (Mortimer *et al.*, 2015). Four media were also assessed for their effect on sperm motility

subpopulations and confirmed procaine hydrochloride as an inducer of hyperactivation in Tankwa goat spermatozoa. Procaine achieved the highest percentage sperm hyperactivation (25.3%), followed by lignocaine (3.4%), whereas PBS (0.1%) and BO sperm wash (0.04%) did not induce hyperactivation.

The standard semen parameters of Tankwa goats in the current study are in the same range that was reported for South African indigenous goats (Bopape *et al.*, 2015; Ramukhithi *et al.*, 2018) and for Saanen, Angora, and British goat breeds (Ahmad & Noakes, 1996; Nur *et al.*, 2005; Talebi *et al.*, 2009). Studies on Norwegian goats (Paulenz *et al.*, 2005) and Florida goats (Hildago *et al.*, 2008) indicated that a highly fertile buck must produce a sperm concentration of $\geq 2000 \times 10^6/\text{mL}$. The Tankwa goat thus falls within this range with a mean sperm concentration of $2293.7 \pm 1853.6 \times 10^6/\text{mL}$. In the present study, percentages of rapid-swimming spermatozoa ($12.8 \pm 11.3\%$, range 2.6–43.1%) and normal sperm morphology ($62.0 \pm 26.3\%$) were lower than those found by Ramukhithi *et al.* (2018) for the same Tankwa goat population ($41.2 \pm 5.9\%$; $93.7 \pm 1.7\%$). This inconsistency is probably owing to a larger sample size, a larger variation in sperm motility and different cut-off values for swimming speed classes in the present study compared with Ramukhithi *et al.* (2018). Moreover, CASA-derived cut-offs were used in the present study to determine percentage normal morphology, whereas Ramukhithi *et al.* (2018) scored morphology manually. A recent study, which used a similar approach to assess rat sperm morphometry and morphology reported a similar discrepancy between manually assessed normal morphology (>90%) and automated analysis (67 - 74%) (Van der Horst *et al.*, 2018b).

All four of the media investigated in the study supported sperm motility, resulting in high percentages of total motility, which is typical of fertile males from domesticated and wildlife species (Van der Horst *et al.*, 2018a; El Kadili *et al.*, 2019). The percentage progressive sperm motility for most media used in the current study (40.0 - 48.9%) was in agreement with data ($44.4 \pm 6.3\%$) reported by Ramukhithi *et al.* (2018), indicating that lignocaine caused a decrease (25.4%) in this motility parameter. The higher percentage rapid-swimming spermatozoa and increased values for VCL and ALH indicated that procaine had a stimulatory effect on Tankwa goat sperm motility, which was confirmed in the many rapid-progressive swimming spermatozoa that were visible in captured fields (Figure 3). Although exposure to lignocaine resulted in more asymmetrical and less linear swimming patterns, there was no increase in the swimming speed typical of mammalian hyperactive motility (Van der Horst *et al.*, 2018a). Boye *et al.* (2019) reported similar decreased progressive motility and LIN in equine spermatozoa after exposure to 100 - 10000 $\mu\text{g}/\text{mL}$ lidocaine, with no induction of hyperactivation. These differences in motility in sperm exposed to lignocaine and procaine justified the use of procaine to determine kinematic cut-off values for Tankwa goat hyperactivation.

The use of cut-off measures for specific sperm head kinematic parameters is a practical and accepted method to define hyperactivated motility in different species (Baumber & Meyers, 2006; Marquez & Suarez, 2008). Of these, a decrease in VSL, STR and LIN values and an increase in VCL and ALH are considered hallmarks for hyperactivated spermatozoa (reviewed by Suarez, 2008; Van der Horst *et al.*, 2018a). For instance, Mortimer and Maxwell (1999) reported VCL (> 250 $\mu\text{m}/\text{s}$), VSL (< 100 $\mu\text{m}/\text{s}$), LIN (< 30%) and ALH (> 9 μm), using the Cartesian method, to be indicative of sperm hyperactivation in rams, which is similar to the seven cut-off values used in the present study. In contrast, Colás *et al.* (2010) induced hyperactivation in ram spermatozoa with caffeine, and used only a decrease in LIN and an increase in ALH as indicators of hyperactivated spermatozoa.

Caffeine (a component of BO sperm wash), lignocaine and procaine (both local anaesthetic agents) have been used to induce hyperactivation in numerous mammalian species by employing various mechanisms of action. Caffeine enhances sperm motility by increasing intracellular calcium by translocation from internal calcium stores (Hong *et al.*, 1985; Ho & Suarez, 2001) or by inhibiting phosphodiesterase, which results in increased cyclic adenosine monophosphate and protein kinase A levels (Garbers *et al.*, 1971; Bender & Beavo, 2006). Lignocaine has been shown to cause an increase in the concentration of intracellular Ca^{2+} in sensory neurons from influx through the plasma membrane and release from Ca^{2+} internal stores (Gould *et al.*, 1998) and to cause sperm hyperactivation in human sperm (Bennett *et al.*, 1992). Hyperactivation induced by procaine has been associated with a moderate increase in intracellular pH, which could activate CatSper channels, followed by influx of extracellular Ca^{2+} (Carlson *et al.*, 2003; Kirichok *et al.*, 2006; Ortgies *et al.*, 2012), or could be directly linked to inhibition of sodium influx (Leemans *et al.*, 2018). Interestingly, procaine-induced hyperactivation in the stallion (Loux *et al.*, 2013) and guinea-pig (Mújica *et al.*, 1994) was shown to be independent of external Ca^{2+} , which is similar to the present results (procaine in PBS). Whereas procaine induced on average 25.3% hyperactivation in Tankwa goat spermatozoa, this was lower than the 73% reported in equine spermatozoa (McPartlin *et al.*, 2009) and the 64% in guinea pig spermatozoa (Mújica *et al.*, 1994). These differences could be because of interspecies differences, the physical environment in which spermatozoa swim, and the kinematic parameters that were used to establish threshold values for hyperactivated spermatozoa (Suarez & Ho, 2003; Van der Horst *et al.*, 2018a).

An average of 25% hyperactivation for Tankwa goats suggested a fertile goat population, since it corresponded to the more than 20% hyperactivation found in other normospermic mammalian samples and human sperm with fertilizing ability (Mortimer & Mortimer, 1990; Van der Horst *et al.*, 2018a). In fact, more than 60% of the individual Tankwa goat samples portrayed more than 20% hyperactivation, albeit a range of 0 - 54% was recorded for the 28 individual semen samples that were assessed. Although this could be an indication of inter-individual variability in sperm functional capabilities and the ability to compete with the spermatozoa of another male, it must be taken into account that only a certain population of spermatozoa will present with the quadrilateral CatSper1 domain organization that is needed to become hyperactivated or capacitated at a certain time Chung *et al.* (2014). Because the percentage hyperactivation induced in the present study correlated with the percentages of progressive and rapid-swimming spermatozoa and VCL and VAP, this indicates that semen samples with high percentage motility would contain sufficient spermatozoa that could become hyperactivated.

Conclusions

The novel approach in this study was to determine cut-off values for kinematic parameters for hyperactivation using CASA combined with ROC curve analysis. After exposing highly motile spermatozoa from semen to various media, PBS and BO sperm wash maintained sperm motility, but were unsuccessful in inducing hyperactivation in Tankwa goat spermatozoa. It is recommended that procaine hydrochloride should be used in future evaluations of potential male fertility in this species. Further, it should be regarded as a rapid diagnostic tool for similar assessments in other animal species. The use of hyperactivation as a test of sperm function might distinguish between breeding and non-breeding males and assist animal production specialists to select males with high sperm functionality.
