Background: In high-income countries (HICs) 17–20% of colorectal cancer (CRC) patients have metastatic CRC (mCRC) at the time of diagnosis, of which 10–25% are or become resectable, and a further 4–11% of patients will develop metachronous metastases. The study aimed to establish the prevalence and pattern of metastatic CRC to document treatment outcomes in KwaZulu-Natal (KZN), and to compare results to international norms.

Methods: The study population comprised patients with mCRC presenting between 2000 and 2019. Demographics, primary tumour site, spectrum of metastatic disease and resection rate were assessed.

Results: mCRC occurred in 33% of the CRC patient population. Eight hundred and thirty-six patients had metastatic disease, comprising Africans (325, 38.8%), Indians (312, 37.3%), Coloureds (37, 4.4%) and Whites (161, 19.2%). Six hundred and fifty-four patients (79%) had synchronous metastases and 182 patients had metachronous metastases (21%). Single organ metastases occurred in 596 patients (71.2%) (M1A) and multiple organ metastasis occurred in 240 patients (28.7%) (M1B). Metastases occurred in the liver (613), lung (240) and peritoneum (85). Fifty-two patients (6.2%) underwent resection of their metastases.

Conclusion: The prevalence of stage IV CRC in our setting is at the upper limit of international norms. mCRC occurred in 33%, with similar proportions in all races. Resection rate for metastases is low.

Keywords: colorectal cancer, stage IV colorectal cancer, resection, metastases

Introduction

Stage IV colorectal cancer (CRC) is defined as CRC with the presence of distant metastases. Approximately 17–20% or more of patients with CRC have metastatic disease at the time of diagnosis, and a further 4–11% will develop metachronous metastases. The liver is the most common site of metastases but this is dependent on the accuracy and resources to stage these patients.¹⁻⁴ In 10–25% of patients with metastatic CRC (mCRC), the metastases become resectable following the use of chemotherapy.² With improving surgical techniques of liver and lung resections in high-income countries (HICs), more patients are becoming candidates for resections.^{5,6}

The public sector in South Africa (SA) is responsible for the care of 80% of the population, while the private sector treats less than 20% of the population.^{7,8} Brand et al. have shown that in the private healthcare sector of SA, only 7.2% of patients with lung and liver metastases from CRC underwent resection for their metastases.⁵ For the majority of CRC patients with metastases in the public healthcare setting in KwaZulu-Natal (KZN), there are limited curative options. A significant benefit in median overall survival (OS) has also been shown internationally with palliative systemic treatment.^{1,8} With the current lack of resources and there being no current public screening initiatives, the

auditing of the public health system is necessary to assess the effectiveness of the health services in this domain and compare the rates of resection and the percentage of patients who receive palliative chemotherapy. A comparison of the metastatic resection and palliative chemotherapy rates between SA and the rest of the world would provide important information around the current standard of care within our country and will quantify the level of input required to match world norms.

Patients and methods

Study setting

The study was carried out at the Durban colorectal unit situated at Inkosi Albert Luthuli Central Hospital (IALCH), a tertiary referral hospital in KZN, SA. It houses the colorectal and oncology units, both of which participate in the gastrointestinal cancer multidisciplinary team (MDT). Additional colorectal and oncology units are situated at Addington Hospital (ADH) in Durban and Grey's Hospital (GH) in Pietermaritzburg, both of which are subsidiaries of the main units at IALCH. GH refers only those patients requiring liver resection to IALCH. All patients with CRC cancer, including palliative cases, are discussed at the MDT meeting, which consists of surgeons, oncologists, and

radiologists, colorectal, hepatopancreato-biliary and cardiothoracic teams. Decisions to resect are made in consensus based on resectability and patient fitness.

Patients

The study included all patients with histologically proven CRC extracted from the CRC database entered between 2000 and 2019. Patients with colonic cancers are generally managed surgically at the regional hospitals and are referred to IALCH only after resection unless they present with complicated disease. Patients with rectal cancers are referred to the multidisciplinary clinic before treatment for management decisions. Exceptions are patients who present at the base hospital with tumour-related complications such as obstruction, perforation, and fistula. These patients undergo the emergency procedure for the primary tumour and are referred to the MDT thereafter. Population groups are defined as African, Indian, Coloured and White according to the criteria used by the South African Government. In SA, “Coloured” refers to people of mixed ancestry.⁹ All patients with stage IV CRC diagnosed on staging CT scan, abdominal ultrasound, MRI or at surgery were included.

Study design

The study is a sub-analysis of prospectively collected data in the CRC registry. The following variables were analysed: age at presentation, gender, race, clinical presentation, site of primary tumour, fixity of the primary tumour, site of metastasis and the management of the primary and secondary tumours. Synchronous metastases were defined as metastases detected at initial diagnosis and/or initial diagnostic work-up, whereas metachronous metastases were considered as those that were detected beyond the time of diagnosis of the primary tumour.¹⁰ Our unit policy for imaging surveillance for metachronous lesions is imaging in the case of development of new symptoms or a rise in the serum carcinoembryonic antigen (CEA). M1A was used to describe metastases to one organ and M1B to more than one organs.¹

Resectable CRC liver metastases were defined as metastatic liver disease in which a R0 resection can be performed, leaving at least 20–25% of total parenchymal volume with adequate inflow, outflow and biliary drainage.¹¹ Local policy is to give neoadjuvant chemotherapy to patients with potentially resectable and borderline metastases. Resectable lesions are resected up front. Currently, we offer liver resection, portal vein embolisation (PVE) and trans arterial chemo-embolisation (TACE). Patients with unresectable metastases are given palliative chemotherapy or only best supportive care if they are in poor general condition based on their ECOG Score.¹² Each patient’s management is individualised to their clinical condition and fitness for surgery. Chemotherapy for stage IV disease in our unit is 5-FU-based with oxaliplatin as first-line combination (Folfox regimen) and irinotecan as second line (Folfori regimen), which is used for both neoadjuvant and adjuvant therapy. We do not have access to biological agents. Cycles can vary between six and 12 depending on patient tolerance and compliance.

Statistical analysis

Data were processed with SPSS 11.5 statistical program for Windows. Pairwise comparison was used to compare metastasis extent by age, ethnicity and gender.

Ethical considerations

All patient data was anonymous and confidentiality for participants was maintained.

Results

Of the 2 521 patients accrued over the inclusion period (2000–2019), 836 (33%) had stage IV CRC. Six hundred and fifty-four patients had synchronously detected metastases and in 182 (21.7%) metastases were detected later (metachronous metastases). The patient characteristics are shown in Table I. The median age at presentation was 59 (range 48–68) years and there were 438 males with a male-to-female ratio of 1:1. African patients were the youngest at the time of presentation compared to the other population groups, with a median age of 52 years. The sites of the primary tumour were colon (392, 46%) or rectum (440, 54%), giving a colon-to-rectum ratio of 1:1.2. Four patients had synchronous primary colonic and rectal lesions. The 836 patients were sub-staged M1A (596, 71.2%) and M1B (240, 28.8%). Table II shows the distribution of metastases. The liver was the most common target organ (73%), followed by the lungs (28%).

Eighty-three patients received neoadjuvant therapy for their metastases, and 195 received adjuvant chemotherapy for their primary lesion after surgical resection (Table III). One hundred and eighteen patients did not receive chemotherapy for various reasons including poor general condition (11), refusal of treatment (6) and failure to return for treatment (3) and the remainder were lost to follow-up or did not attend

Table I: Characteristics of patients with stage IV colorectal cancer

	n (%)	Median age (IQR)
Overall (n = 2 521)	836 (33%)	59 (48–68)
African (n = 943)	325 (38%)	52 (40–65)
Indian (n = 982)	312 (37%)	58 (49–68)
Coloured (n = 116)	37 (4%)	59 (53–67)
White (n = 472)	161 (19%)	66 (59–75)
≤ 40 years (n = 333)	123 (15%)	
> 40 years (n = 2 182)	713 (85%)	

Table II: Distribution of metastases

	Total mets n (%)	Synchronous mets (n)	Metachronous mets (n)
Overall	836 (100%)	654 (78%)	182 (22%)
Liver	613 (73%)	499	114
Lung	240 (28%)	177	63
Peritoneum	85 (10%)	75	10
Bone	50 (6%)	35	15
Omentum	33 (4%)	28	5
Ovaries	28 (3%)	26	2
Distant LN	29 (3%)	24	5
Pleura	8 (1%)	6	2
Testis	1 (1%)	1	0

LN – lymph nodes, mets – metastases

Table III: Management of metastases

Patient management	Metastases (n = 836)	Synchronous (n = 654)	Metachronous (n = 182)
Neoadjuvant therapy for metastases	83 (10%)	79 (9.5%)	4 (0.5%)
Upfront resection of primary	54 (6%)	44 (5%)	119 (14%)
Adjuvant chemotherapy	195 (23%)	98 (12%)	97 (12%)
Palliative chemotherapy	434 (52%)	414 (49.5%)	20 (2%)
Resection of metastases	52 (6%)	39 (5%)	4 (1%)
Liver resections	36 (4%)	27 (4%)	9 (1%)
Other	16 (2%)	14 (2%)	2 (1%)
Oncological therapy not received	118 (14%)	83 (10%)	35 (4%)

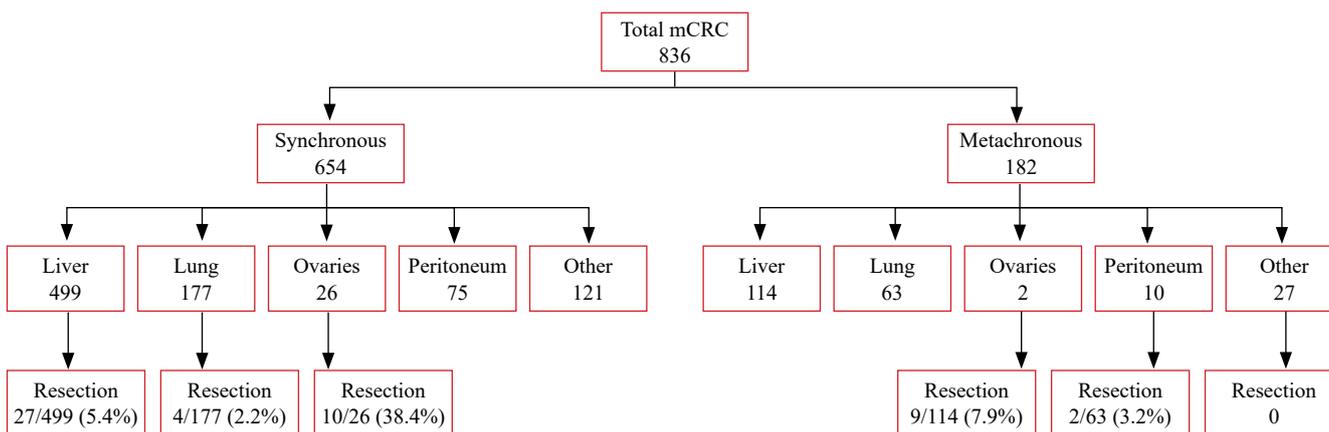

Figure 1: Flow diagram of mCRC distribution and resection of metastases

their first oncology appointment. The remaining patients ($n = 434$) received palliative chemotherapy. Eighty-three patients started with neoadjuvant therapy for metastases, but 35 did not respond to therapy and were converted to palliative. A total of 214 patients (25.7%) were lost to follow-up.

Resection of metastases was performed in 52 (6.2%) patients, with liver resections in 36 (4%) patients, oophorectomy in 10 (1%), and lung resection in six (1%) (Figure 1). In the synchronous and metachronous groups 27 (4%) and nine (5%) liver resections were performed, respectively. Two patients with liver metastases received chemo-embolisation, two received microwave ablation and one received radio-frequency ablation. None of these radiology-guided interventions were followed by a liver resection. Lung resections were performed in four patients within the synchronous group and two within the metachronous group. Oophorectomy was performed in 10 patients within the synchronous group.

Discussion

In our study, the anatomical location of the primary tumour was shown to mimic international trends, with the rectum being the most common site.¹³ mCRC accounted for 33% of patients with CRC, which is higher than the 17–20% reported in the international literature.¹⁴ The fact that stage IV disease occurred similarly in younger (≤ 40 years) and older patients (> 40 years) underscores the potential for similar disease progression in young and old presenters, however, this remains controversial and is a subject of debate.¹⁴ Males and females had equal distribution of mCRC. The liver accounted for 73% of the overall metastatic burden, which is similar to previous reports of 70%.¹⁵ Seventy-one per cent

of the patients were staged M1A. The lungs were the second most common site (28%), which is higher than the 10–15% reported in the literature.⁶ In our series, the most common combination of metastases in M1B patients was liver and lung metastases, which occurred in 122 patients (14%).

The management of stage IV CRC is improving with aggressive surgical resection and better chemotherapeutic agents resulting in improved survival. Approximately 75% of patients with stage IV CRC referred to specialist centres are considered unresectable at presentation prior to the institution of chemotherapy.¹⁶ Liver resection offers the chance of potential cure for patients with colorectal liver metastases. The definition of potentially and borderline resectability has yet to be universally defined.¹⁷ Some authors use the definition of potentially resectable metastases as R0 resection being compromised as a result of a large tumour burden, but the volume, outflow, inflow and biliary drainage of the future liver remnant (FLR) were considered adequate and the patient would benefit from systemic therapy and restaging.¹¹ Borderline resectable means the possibility of radical resection but, compared to initially resectable, it is considered to be difficult oncologically and technically.¹⁷ Only 36 patients (4%) were offered liver resection of metastases in this series, which is below the 25% reported in the international literature and lower than the 10% reported in the private sector in SA.^{5,18} The reasons for the low liver resection rate in our unit are multi-factorial, including patient refusal for further surgery or chemotherapy, advanced disease, lack of biological agents and high attrition rates. Radio-frequency ablation, microwave ablation and trans-arterial chemo-embolisation for the treatment of liver metastases are available in the state sector in SA, but to a limited extent for selected cases.¹⁹

There are no clear criteria for surgical resection pulmonary metastases.²⁰ However, pulmonary resection is regarded as the standard of care for resectable pulmonary metastases based on results of retrospective studies.²⁰ Resection of multiple lung lesions is associated with poor surgical outcomes compared with solitary lesions. Resection of two to four lesions can be considered if the primary tumour has been treated and the patient has sufficient lung function.²¹ Only 2% of patients with lung metastases were resected, which is much lower than previously reported rates of 21%.²¹ Resection of solitary lung metastases is associated with low morbidity and mortality and 5-year survival rates of 21–63%.^{6,22} Stereotactic radiation and local ablation have been shown to be curative in smaller tumours. Our resection rate is low comparatively because most patients being M1B with simultaneous lung and liver metastases and had multiple rather than solitary lesions precluding them from surgery. Another compounding factor is patient reluctance to undergo further surgery. Currently used chemotherapeutic agents for lung metastases seems to be as effective as in the liver.²¹

Peritoneal carcinomatosis secondary to CRC occurs in 4–5% of patients with stage IV.²³ The peritoneal cavity has been shown to be the only site of metastatic disease in approximately 25% of patients with metastases,¹³ leading some to postulate that peritoneal carcinomatosis may represent a first site of dissemination in some cases, and is therefore not necessarily indicative of generalised disease.²⁴ Recent data suggest that long-term survival can be achieved using aggressive cytoreductive surgery followed by hyperthermic intraperitoneal chemotherapy (HIPEC) which is used in some centres of excellence.^{25,26} We currently do not have this facility in our unit.

Only 3% of patients had isolated ovarian metastases which is comparable to the 1–4% reported in the literature.²⁷ Whereas ovarian metastases have been reported to be more common in premenopausal women, with the colon as the site of the primary tumour, in our series it was more commonly seen in postmenopausal women with the rectum as the primary site.²⁸ Resection is associated with fairly low morbidity and may improve quality of life and prolong survival, even in the setting of widespread extra-ovarian metastatic disease.²⁸ Only 38.4% of patients with ovarian metastases in this series underwent oophorectomy, compared to as many as 77% of patients with isolated ovarian metastases in reported series.²⁹

The reasons for the low resection rates in our series, including poor patient compliance regarding follow-up and treatment, delayed presentation, and patient unwillingness to undergo surgical intervention need to be addressed. Dedicated MDT meetings which have been shown to have substantial impact on patient management, need to be established.³⁰ Ideally, all patients should be discussed in an MDT meeting to optimise decision-making.

Access to oncological resources for all patients within a reasonable timeframe to facilitate early diagnosis and management will improve the resection rate. Adequate subspecialty training in SA needs to be fostered for general surgeons, this will facilitate more skilled surgeons to address the volume of metastatic resections. With an increase in volume of cases, the complexity of cases that can be dealt with will also increase and more patients will be offered resection. The improved combination chemotherapy regimens used in the treatment of patients with advanced CRC can facilitate

the downsizing of colorectal liver metastases and render initially unresectable metastases resectable.^{1,27,28} Access to newer and more effective chemotherapeutic and biological agents has substantially improved survival and quality of life for patients with stage IV disease.³³ These agents are not readily available in the public sector in SA.

Our study does have some limitations. The database reflects a single academic institution and the three affiliated tertiary hospitals. Some patients with a diagnosis of CRC may have refused hospital admission and therefore not referred to the three main tertiary hospitals or may have succumbed to their illness prior to referral. Under-diagnosis does therefore remain a possibility. These findings relate to patients in the KZN region and should not be generalised to the rest of SA. The strength of the study is that it is one of the largest gastrointestinal (GI) cancer registries in an African country.

Conclusion

The prevalence of mCRC in our setting is at the upper limit of international norms. Resection rate for metastases in SA is very much lower than international norms. Access to newer chemotherapeutic agents and aggressive metastatic resection need to be encouraged to improve survival. Patient compliance and adherence needs to be improved with efficient accessibility to oncological units. Our local units need further funding and research to improve outcomes.
