## Assessment of Risk Factors Related to Body Pain Complaints in Tanzania Construction Industry

Fatma K. Mohamed

\*Department of Structural and Construction Engineering, University of Dar es Salaam, P.O. Box 35131, Corresponding author: fatmamo@udsm.ac.tz ORCID: https://orcid.org/ 0000-0002-9704-5349

#### ABSTRACT

The construction industry is associated with risks that can result in	ARTICLE INFO
musculoskeletal diseases. Although young male workers who are	Submitted: Sep. 26,
presumed to be healthy dominate the industry in Tanzania, body pain complaints have been widely reported. The aim of this study is to assess	2023
the prevalence and causes of body pains in workers. A cross-sectional study involving 306 workers was conducted A chi square test was used	Revised: March 20,
for testing association of independent categorical variables and binary	2024
logistic regression analysis was used to determine predictors for body	Accepted: Apr. 15,
pain complaints. The results show that all study participants complained	2024
of at least one form of body pain with back pain at 87.0%, shoulder pain at 62.9% and neck pain at 25.8% Both sociodemographic factors as well	D 11 1 1 A 2024
as biomechanical risks factors were found to be determinants for pain in	Published: Apr., 2024
the neck and shoulder. However, none of the factors were found to be statistically significant for back pain.

#### **INTRODUCTION**

Construction industry has been shown to have a very strong relationship with countries' gross domestic product (Alaloul et al., 2021; Musarat et al., 2020) and said to employ over 7% of the world's entire workforce (ILO, 2019; Kanchana et al., 2015). However, the industry is considered as one of the most hazardous industries for work-related musculoskeletal symptoms (Guo et al., 2004; Chen et al., 2005) where globally the prevalence of musculoskeletal disorder symptoms involving one or more body regions is higher in construction workers compared to other industries (Liang et al., 2019, Sousa et al., 2014). Seventy-seven per cent of the total construction workers are recognized to have musculoskeletal pain or disorder (Shirur et al., 2014) with the low back, neck, and upper extremities being the most commonly affected body parts (Umar et al., 2020; Umer et al., 2018; Alghadir and Anwer, 2015). Musculoskeletal disorders in the construction industry are mainly a factor of sociodemographic and ergonomic risk factors (Jaffar et al., 2011; Choi, 2010). Sociodemographic risk factors associated with body pain: Differences in perception of risks may lead to exposure that may in turn lead to accidents, injuries, body pain and musculoskeletal diseases. Studies show that workers perceive risks differently even when exposed to identical circumstances (Ricci et al., 2021; Trillo-Cabello et al., due to differences in their 2021)

influencing sociodemographic factors (Renault et al., 2021; Chaswa et al., 2020). Studies by Chen and Jin (2015) in United States of America, Idrees (2017) in Pakistan, Meng and Chan (2020) in China, have shown that age plays an important role awareness and in situational safety perception whilst a study by Han et al. (2019a) shows that there is a significant influence to safety perceptions in relation to difference in age, sex and educational level. The study found that young female workers with low-level education have lower safety perceptions compared to their peers on the same work environment. Han et al (2019b) also shows that workers' experience has a significant impact to the perception of safety in construction industry where entrylevel employees tend to evaluate hazards with a higher degree of danger compared to early career employees and senior peers.

Other studies have shown that sociodemographic factors such as marital status (Berhanu et al., 2019; Fang et al., 2006) work role/type, work experience, education, employment status, and training also influence workers situational awareness (Meng and Chan, 2020: Mahboobi et al., 2020; Karimi and Taghaddos, 2019; Chan et al., 2017).

The construction industry involves variety of workers who perform activities in different environments such as at heights, on ground or underground (Ekpenyong and Inyang, 2014) facing chemical, biological, physical, psychological, biomechanical and ergonomic risks that might cause injuries to bodies (Jaffar al.. their et 2011). Biomechanical risk is physical, a physiological, environmental factor within the workplace that harms the musculoskeletal system of the workers (Anwer et al., 2021; Liang et al., 2019; Shirur et al., 2014). Construction workers find themselves exposed to various biomechanical risk factors including lifting and carrying of heavy loads, prolonged vibration, bending, kneeling and other awkward postures (Antwi-Afari et al., 2017; Salas et al., 2016). A study by Lop

al. (2019) found that repetition et movement, awkward posture, forceful exertion, vibration and contact stress are all risk factors to concrete workers in Malaysia where awkward posture was found to be one of the biggest contributing factors musculoskeletal related to injury. Occupational exposure to vibration and awkward posture were also associated with shoulder and neck musculoskeletal disease in a study by Charles et al. (2018). On the other hand, loading forces have been associated with risk of injury at the shoulder, neck, lower back, forearm, wrist and hand (Ray et al., 2012). In general, biomechanical risk factors are dependent on working procedures and methods used in the construction site and can lead to musculoskeletal diseases.

The construction industry in Tanzania contributed 13.8 percent of the total gross domestic product in 2021 with an annual growth rate of 2.3 percent (URT, 2021). As other developing countries, the industry is proliferated with unskilled parttime labour (at least 70 to 75 percent) with low engagement of female workers at 14.5 to 24.7 percent depending on the size of the construction company (URT, 2010). While studies have been conducted in different countries on the prevalence of body pain in construction industry the and their associated risk factors, it should be noted that the two are likely to be country specific since the construction industry in different countries is governed by different laws and has different levels procedures. of organizational maturity employs and workers with different skill set. Moreover, the impact of sociodemographic factors is not transversal to all construction industries, therefore there is a need to understand the impact of these factors specific to Tanzania construction industry.

## METHODS AND MATERIALS

## Study Design

Cross-sectional design was used to investigate exposure to biomechanical risk

factors and outcomes (neck, shoulder, and back pain) among construction workers in the economic capital of Tanzania – Dar es Salaam from 20<sup>th</sup> January 2020 to 30<sup>th</sup> May 2020. The study also investigated the effect of sociodemographic factors on pain complaints among workers.

#### **Study Sample**

The required sample size was determined by using the single population proportion formula (Israel,1992):

$$N = \frac{Z^2 x P x Q}{E^2}$$
(1)

where N is the desired sample; P = Population proportional (0.533 - the proportion of workers who experienced body pain as reported by Jazari et al. (2018); Z = Confidence level (Z = 1.96 for 95%); E = Margin of error 5% (0.05); Q = (1-P).

Since the study used simple random sampling technique, a total of 10% anticipated non-respondents was added to give a total of 424 respondents needed in the study. The researchers visited eighty (80) registered construction sites having skilled and unskilled workers and selected five participants at random working at each site. Information was collected from 396 workers from a total of 424 workers that were selected (93.4% response rate) surpassing the required sample size of 385 workers. Ethical clearance was first obtained from the University of Dar es Salaam through the Department of Structural and Construction Engineering, Contractors Registration Board - that registers construction all projects, Construction companies' site management and oral informed consent was obtained from each respondent prior to answering the questionnaire.

## Questionnaire design

A pre-tested and structured questionnaire and observational checklist were used to collect data on the prevalence of body pain complaints and its associated risk factors (Yang et al., 2020; Mekonnen et al., 2020; Reddy et al., 2016; Ekpenyong et al., 2014) using trained personnel. The anticipated sociodemographic and biomechanical risk data to be collected was referenced from literature review.

The first part of the questionnaire recorded information detailed on the sociodemographic condition of the participants including sex, age, education (no formal education, primary education, secondary education and higher education), marital status (single, married, divorced, cohabited, widower) employment status (temporary, permanent), and work experience (three to six months, six to twelve months and above twelve months). Due to a possibility of having a majority of temporary workers in the industry, work experience was defined in shorter periods of time in order to understand the working habits of these workers. The second part focused on information related to biomechanical risk factors. This information looked at the characteristics of the tasks performed by the workers (prolonged squatting, moving heavy loads manually, extension of arms, repetitive motion, bending and working with vibration tools) and the working method (work rotation). The third part of the questionnaire extracted information on the body regions where they have experienced pain in the last twelve months of working in the construction industry, whilst the fourth and final part of the questionnaire asked on the knowledge related to ergonomic risks and perceived measures to combat the risks.

Here, prolonged squatting was taken to mean working while squatting for more than thirty minutes without change of posture whilst moving the standard 20kg sandcrete block was used as reference when referring to moving of heavy loads manually. Repetition could be defined as performing a task that uses the same muscles over and over with little chance for rest or recovery (Jaffar et al., 2011); this includes task such as painting and moving buckets of water. On the other hand, neck and back bents involves tasks that are performed while the neck and back are bent at an angle causing strain to the muscles. On the other hand, work rotation is defined as change of task to another discipline periodically.

### Data analysis

Data collected were sorted and checked on daily basis to check their completeness and consistence. It was then statistically using analvzed SPSS version 22. Demographic data of the participants were calculated using descriptive statistics. Prevalence of body pain in different body regions was determined using cumulative frequency. Chi square tests were used for testing association of independent categorical variables (sociodemographic and biomechanical factors) and outcome variable (body pain complaints) using univariate analysis.

Binary logistic regression analysis was then used to determine predictors for body pain using odds ratio (OR) and confidence interval (CI) of 95%. P value <0.05 was considered statistically significant. The regression analysis included only the variables found to be significantly associated with body pain in the univariate analysis. Logistic regression analysis was chosen because it is well suited for describing and testing hypotheses about relationships between categorical a outcome and one or more categorical or continuous predictors (Peng et al., 2002). It has also been widely used in studies analyzing risk factors associated with occupational safety (Halabi et al., 2022; Makki and Mosly, 2021; Amoako et al., 2020; Chau et al., 2003). To investigate the reliability of the binary logistic regression, pre-estimate tests were performed to ensure linear relationship there is between

continuous independent variable and the logit transformation of the dependent variable. The natural logarithm of the continuous independent variable was found not to be statistically significant and hence the data was assumed to be reliable.

#### Results

**Participants** socio-demographic information: In this study, the mean age of study participants was found to be 35.9 years. As a representative of the construction industry in Tanzania, the population was skewed to the male respondents (84.6%) with almost an equal distribution of respondents who were single (46.0%) and those who were married (42.9%). In addition, more than three quarters of respondents (77.5%) were temporarily employed. Workers who have lower-level education – primary school (37.1%) and secondary school (52.8%), dominate the industry whilst workers with higher education make only 8.1% of the study population. Moreover, the industry is made mostly of workers who have an experience of more than one year (76%)(Table 1).

The socio-demographic information collected in this study is consistent with the general characteristic of the construction industry in Tanzania as explained in Section 1.4 giving validity to the sampling method used in this study.

#### Prevalence of body pain complaints

The study participants reported three body pain complaints – back, shoulder and neck pain. All respondents reported pain at one or more body regions in the last twelve months. The most frequent body pain complaint was back pain at 87.6%, followed by shoulder pain at 62.9% and neck pain at 25.8% (Figure 1).

Risk factors in relation to body pain complaints

\_

Risk factors associated with body pain complaints

173

The results in Table 2, Table 3 and Table 4 show association between risk factors and body pain complaints for neck, shoulders and back respectively. The results show strong association between all sociodemographic factors and neck, shoulder and back pain with the exception of employment status for back pain. On the other hand, only manual lifting, work rotation, extension of arms, prolonged squatting and moving more than 20kg load show an association with back pain amongst biomechanical factors. For the case of biomechanical risk factors on neck

pain, work rotation, and bent back show no association whilst working with vibrating tools, repetitive motion and moving more than 5kg load show a strong association with p<0.01.

Contrarily, all biomechanical risk factors show an association with shoulder pain except for moving more than 20kg load. All factors that showed a strong degree of association with body pain (p-value <0.05) in this univariate analysis were inputted as covariates in the multiple regression analysis model that determined significant risk factors to body pain.

# Significance of risk factors to body pain complaints

The results showing significant risk factors for neck pain are given in Table 5. Sociodemographic factors related to age, sex, education, employment status and work experience show a significant relationship with neck pain whilst extension of arms, repetitive motion and moving more than 20kg load are significant factors among biomechanical risk factors. In the case of shoulder pain, none of the sociodemographic factors are significant but extension of arms, prolonged squatting, works rotation, repetitive motion and working with vibration tools are all found to be significant among biomechanical risk factors (Table 6). Contrarily, all sociodemographic and biomechanical risk factors were found to be statistically nonsignificant for back pain (Table 7).

Additionally, in order to understand the relationship between age, experience and doing heavy manual jobs such as moving more than 20kg load, a correlation analysis was conducted between the three factors (Table 8). The same analysis was also conducted to elicit the relationship between education, experience and moving more than 20kg load (Table 9). The results show that there is an inverse correlation relationship between decreasing age of worker and experience and moving more than 20kg load and decreasing age of worker. Moreover, the results in Table 9

show that there is an inverse relationship between education and experience and between moving more than 20kg and experience but a positive relationship between education and moving more than 20kg load.

## **RESULTS AND DISCUSSION**

The present study was conducted in an attempt to investigate the working conditions of construction workers in Tanzania and evaluate the prevalence of musculoskeletal pain and their contributing risk factors. The study revealed that all workers investigated (100%)had experienced at least one form of body pain in the last twelve months of work with pain of the back being the most prevalent similar to previous findings amongst construction workers in other countries, albeit the findings in Tanzania show a significantly higher prevalence compared to Saudi self-reported, Arabia (48.5%, last 12months) (Alghadir et al., 2015), Iran (53.3%, self-reported, last 12months) (Jazari et al., 2018), Netherlands (67%, self-reported, last 6 months) (Boschman et al., 2012), and Nigeria (39.25%, selfreported, last 12months, Nordic scale) (Ekpenyong et al., 2015). The higher prevalence in Tanzania may be attributed to inadequate breaks and work rotations that would likely offer workers opportunity to work periodically in different fields. Survey results revealed that only 18.7% of study participants doing were work

rotation. Although slightly, work rotation has been shown in this study to decrease

body pain with OR of 0.052 for shoulder pain.

#### Table 7: Significant risk factors for back pain using multiple regression analysis

Moreover, the presence of high number of temporary workers (77.5%) may also be an attributing factor since temporary workers have been found to take less precaution on health and safety issues as they are not assured of employment (Lette et al, 2018). This study found that the relationship between neck complaint and employment status has an OR of 77.677 indicating the markedly increased likelihood for a temporary worker to experience neck pain compared to a permanent one.

Another contributing factor is the differences in activities performed. Studies

show that manual handling activities have significant impact on the body pain complaints (Jazari et al., 2018; Kisilu et al., 2017; Kincl et al., 2016; Ekpenyong and Inyang, 2014; Boschman et al., 2012). In this study, moving more than 20kg load was found to be a statistically significant risk factor for neck pain albeit with a very low odds ratio (p=0.001; OR=0.00). The study of Kisilu et al. (2017) that reported a 22% prevalence body pain complaint has 25.5% of its participants performing manual handling work while in this study it accounted for 90.2%. The implication of this finding is that even contractors with more resources registered in Class I to IV are working without utilization of mechanical tools in contrast to the recommendations Contractors of **Registration Board.** 

Moreover, construction workers are predominately temporarily employed in the construction industry in Tanzania, and continue working under temporary conditions for at least over one year (76%); as a consequence, length of service is another significant risk factor to musculoskeletal diseases among construction workers (Jaiswal & Veerkumar, 2016; Purani et al., 2016) as supported in our results for neck pain (p=0.041).

By understanding the importance of safety training in reducing hazard risks in the construction industry (Tezel et al., 2021; Hasanzadeh et al., 2020; He et al., 2019), the Occupational Safety and Health (Building and Construction Industry) Rules of 2015 (URT, 2015) governing the construction industry in the country under the Occupational Safety and Health Act of 2003 (URT, 2003) requires that the contractor shall provide Occupational Health and Safely training for workers before commencement of the project and that no contractor shall allow or permit any employee or person to enter any site, unless such employee or person has undergone

health and safety induction training pertaining to the hazards prevalent on the site at the time of entry. Regardless of the available regulations, this study found that none of the 396 respondents (0%) working on eighty legally registered construction sites have undergone such a training and that only 3.5% of the participants were aware of ergonomic risks.

After adjusting for all associated variables, age (OR 0.104 for workers of above 30 years of age), sex (OR 7.701 for male workers), employment pattern (OR 77.677 for temporary employed), and work experience (OR 7.292 for duration of 3-6 months and OR 2.495 for duration of 6-12 months) all show a significant contribution to neck pain.

In general, the results show that young male workers under temporary employment with little experience have higher chances of experiencing neck pain since strong young male workers with shorter experience are considered more susceptible to be tasked with heavy manual jobs such as moving more than 20kg load. The results in this study that show that age of above 30 years is a protective factor to body pain are in contrast to the study by Bodhare (2011) and Holmstrom et al. (2005) which found that increasing age is significant risk factor that may be a reflection of the accumulation of repeated insults to the body. However, site procedures in Tanzania, supports the findings of this study. This is because as workers' age increases, their experience and seniority give them an opportunity to be assigned different tasks than doing heavy manual work. This is supported by interpretation of correlation analysis of age, experience and moving more than 20kg load as given in Table 8. Meaning that an experienced worker doing block walling might be tasked with setting of the mortar between blocks while an inexperienced worker is more likely to be tasked with carrying the blocks to the walling area.

Correlated Variable	Type of Correlational Relation	Pearson	Significance	Interpretation
Age (reference category - Below 30 yrs /Above 30 yrs) & Experience (reference category - Above 12 months / 3 to 12 months)	Inverse	-0.184	0.000	Persons above 30 years have experience of over 12 months. Persons of below 30 years have experience of between 3 to 12 months.
Moving >20kg load (reference category - No / Yes) & Experience (reference category - Above 12 months / 3 to 12 months)	Inverse	-0.119	0.018	Persons moving >20kg load have experience of over 12 months. Persons not moving >20kg load have experience of between 3 to 12 months.
Moving >20kg load (reference category - No / Yes) & Age (reference category - Below 30 yrs /Above 30 yrs)	Inverse	-0.020	0.691	Persons not moving >20kg load have age of over 30 years. Persons moving >20kg of load have age of below 30 years

Additionally, education was found to have aunderstanding of doing the task while also small yet significant protective effect for neckimproving on their muscle strength. This kind pain with p<0.001 (OR=0.00) for primaryof observation is supported by medical studies education and p<0.001 (OR=0.00) forof athletes including that of Suchomel et al., secondary education. Although much more2016; Lehance et al., 2009; Portero et al., 2001; detailed research is needed to conclude thisLehnhard, 1996 that show that neck muscles finding, workers with lower-level education aregain strength and ultimately reduced injuries more susceptible to be assigned the task ofafter prolonged neck exercises by athletes. The moving more than 20kg load and ultimatelyreason for the risk effect of higher education on gain experience of doing the same task for atneck pain was not able to be concluded in this least more than 12 months (Table 9). Longerstudy and further research is proposed experience improves on their ergonomic

Table 9:	Correlation	analysis for	education,	experience and	l moving	>20kg load
		•	,	1		0

Education (reference category - Tertiary Education / Secondary Education / Primary Education ) & Moving 20kg load (reference category - No / Yes )	Positive	0.175	0.000	Workers moving >20 kg load have primary education. Persons not moving >20kg load have tertiary education.

Looking at the biomechanical factors, results show that extension of arms (OR 48.742 for neck pain and OR 8.706 for shoulder pain), repetitive motion (OR 416.303 for neck pain and OR 35.142 for shoulder pain) and working with vibrating tools (OR 21.433 for shoulder pain) are significant factors to body pain. These findings are supported by the study done in Karimnagar, Andhra Pradesh and reported by Bodhare et al. (2011) as well as the one reported by Jaiswal and Veerkumar (2016). Their studies revealed stronger a association between body pain and work involving repetitive motion, force extension and working in vibration.

On the other hand, work rotations (OR 0.052 for shoulder pain) that involves change of tasks periodically and prolonged squatting (OR 0.059 for shoulder pain) are protective factors to body pain. These results indicate that workers who have opportunity to work in different fields within the site periodically such as tiling, roofing, walling and painting have lower risks of developing shoulder pain as compared to the ones who work throughout in the same channel that affect the shoulders. Although this is a protective factor to body pain, this study found that only 18.7% of workers studied undergo work rotations. On the other hand, prolonged squatting as a protector of shoulder pain indicates specialization of workers in the site. Workers who have to undergo prolonged squatting in works such as floor tiling specialize in the same tasks and will not be working in fields that can have an impact on the shoulders.

Although back pain is the most prevalent complaint (87.6%) pain among construction workers in this study, none of the identified risk factors showed a significant contribution. This might be an indication that back pain is a product of statistically non-significant multiple factors, yet to be identified factors or not an independent factor from neck and shoulder pain but may be a secondary pain complaint. Nature of doing work in the construction sites in Tanzania supports this hypothesis where heavy objects such as sandcrete blocks, cement sacks, sand and concrete mixing trays/pans within the site are carried on the head or shoulder.

These results show that although the industry is characterized by seemingly healthy young male workers (average age is 35.9; 84.6% male), the work culture and working conditions are major influences to body pain complaints and musculoskeletal diseases in construction workers in the country. Even workers under a work period of less than one year, have reported body pain complaints. Excessive manual handling of works, working under temporary status coupled with site procedural conditions such as extension of arms for long periods with no breaks or work rotations will eventually lead to more severe results adversely affecting the work force. Moreover, lack of enforcement of regulations by authorities has also been shown to be a contributing factor to risks of musculoskeletal disease in the construction industry in Tanzania.

Notwithstanding several limitations to be taken into consideration including the cross-sectional design nature of the study that renders it difficult to draw a causal inference, recall bias arising from selfreported questionnaires with twelve months recall period and reporting bias of symptomatic workers, findings from this that musculoskeletal study confirm diseases are an occupational health hazard in the construction industry in Tanzania. It should be noted that this study was conducted on only registered construction sites that are periodically monitored by government authorities and the situation for unregistered construction work is unknown albeit expected to be in a more severe condition. The study affirms the need to reform the construction industry by enforcing the current regulations that require use of tools and machinery to reduce manual handling and safety training that includes ergonomic risks awareness. Preventive measures including work rotation and frequent breaks should also be reinforced in the regulations. The case of massive temporary employment condition within the industry should also be taken in consideration while devising policies to improve work conditions in the industry.

#### CONCLUSION

In conclusion, musculoskeletal pain complaints among construction workers in Dar es Salaam, Tanzania were found to be highly prevalent where all workers had endured at least one form of body pain throughout their employment. Higher odds of body pain were associated with extension of the arms, repetitive motion, working with vibration tools and moving load of more than 20kg as well as sex, age, experience and temporary work employment conditions. Conversely, work rotation was found to be protective against body pain complains. The study implies that there is a significant and serious risk to construction workers in Tanzania as a result of sociodemographic conditions and a number of biomechanical factors as a consequence of construction process and

procedures involved in construction sites. Authorities have a responsibility to improve business environment that would enable contractors to employ on permanent basis and enforce laws and regulations.
